face on a mask; the ears may conveniently be dressed with cotton wool so saturated that a sort of putty is formed. This acts not only as a dressing but also as a sort of splint, immobilizing the affected part.

A few general observations on what should perhaps be called the seborrheic diathesis may not be out of place, since it modified and profoundly influenced so many of the skin affections met with in the soldier in France. For example, in the treatment of scabies, irritable rashes more commonly followed the application of sulphur, even when properly limited to three days, than is usual in civil life. These eruptions, generally alluded to as sulphur dermatitis, occurred chiefly over areas of friction or pressure, such as the outer thighs, arms, and shoulders. Their appearance was often separated from the last sulphur application by a latent period of from four to seven days. As has already been pointed out they were not always caused by sulphur and indeed it was often easy to demonstrate their presence in some degree in extensive cases of scabies and pediculosis especially when the two conditions coexisted. Naturally sulphur caused some aggravation, but its employment was necessary to remove the causal condition after which their disappearance was hastened by any simple remedy. The tendency to this dermatitis existed throughout the British army, and it was so easily evoked that it came to complicate a variety of conditions besides scabies. The cause remains entirely mysterious. As it cannot be attributed altogether to external conditions, an explanation may be found in the introduction into, or exclusion from, the diet of some substance. The army ration, while admirably adjusted as regards its caloric values, was poor in vitamines and might permit of the occurrence of scurvy unless supplemented; indeed a small outbreak of scurvy was actually met with among some natives who subsisted entirely on the ration. In this connection, an interesting observation by J. M. Little[5] may be quoted. According to this authority beriberi and scurvy, two well-known vitamine deficiency diseases, are common among the Esquimos. They also suffer from a peculiar affection of the skin, known as kallak, an itchy disorder affecting the hands, elbows, buttocks, and other parts. In this disease secondary pyodermia is common. Cure is brought about by giving fresh seal-meat and berries, and for this and other reasons the author attributes the disease to an absence of fat-soluble vitamines.

Here we have two things for consideration: first, the insufficiency in the soldier's diet of vitamines, and second, knowledge that a dermatitis may arise from this cause, facts which taken together form the basis of a tempting hypothesis.

Dermatitis from Gas.—No account of the cutaneous affections in the war would be complete unless it included some reference to the effects upon the skin of mustard gas. While the mask protected the eyes, face, and respiratory passages, no covering could completely prevent this irritating substance from reaching and burning the skin. Its main effects were found over the flexures, neck, back, and scrotum; in the last situation relatively severe dermatitis often occurred. The appearances varied from simple erythema to edema and blistering. Secondary infections might complicate and prolong the course. After all acute symptoms had passed off a brown pigmentation remained which might persist for some considerable time. In its milder degrees the condition approximated very nearly in its effect and appearances to chrysarobin dermatitis. Simple boric ointment seemed to act well in most cases unless infection was present, when the usual surgical measures should be employed.

The above notes briefly record some of the aspects presenting themselves to a dermatologist in the army. Naturally parasitic affections claim first place as they provided the largest field for prevention and observation. Diseases such as psoriasis, acne, lupus vulgaris, etc., were also seen, but they presented no novel features nor were they met with in sufficiently large numbers to be of importance as a cause of wastage in the fighting force.

It has been shown how severe and extensive scabies became, and this was the case not only in the British army but among the allied troops also. Assuming the truth of the arguments already given, this disease may be regarded as largely preventable. There must have been times when the men transferred to hospitals in England or to the bases in France on account of this complaint would have proved of supreme value in the fighting line. The same is true but to a much less degree in the case of pediculosis. Therefore, while every specialist tends to place too high a value on his own branch of medicine or surgery, the importance of the part played by skin disease, and its effects upon the health of the army, justify the belief that the scope of dermatology is considerable in warfare and that experts can do much to preserve man-power and lessen disease.

Medicolegal Notes.

Hypothetical Questions.—The rule in California is that, while a hypothetical question must be based upon facts claimed to be shown by evidence in the case, it is not essential that it embrace all the evidence in the case upon the subject of inquiry, that it may be addressed to any reasonable theory which may be adopted by counsel, and that counsel has the right to frame a question to accord with his theory of what the material facts are as shown by that evidence, and in so doing may omit facts which, from his point of view, have no material bearing upon the subject under inquiry. Of course, counsel for the other side has the right on cross-examination to question these expert witnesses fully as to the effect of such additional facts as he deems shown by the evidence and material to the issue. —People v. Denman, California Supreme Court, 177 Pac. 461.

Revocation of License.—The Colorado Supreme Court holds that the state board of medical examiners had jurisdiction of the question of the revocation of a physician's license and of the person of the physician, and did not exceed its jurisdiction or abuse its discretion in revoking his license upon satisfactory proof of his having committed an abortion. Under the Colorado statutes the inquiry by the court on certiorari could not be extended beyond the jurisdiction of the board to include a review upon the merits by holding that the board was bound to accept his acquittal of the same charge in the criminal court.—State Board of Medical Examiners v. Noble, Colorado Supreme Court, 177 Pac. 141.

DOUBLE EMPYEMA IN CHILDHOOD.

IN every case of empyema in a child, when an aggravation in the symptoms occurs, the other side of the chest should be carefully examined. Pulmonary symptoms on the uninvolved side do not always exist and it is an acknowledged fact that an empyema may become double following an inflammatory process in a single lung. In other cases both pleural cavities are almost simultaneously involved and when the empyema is due to the streptococcus, staphylococcus, or *Bacterium coli* the evolution is ordinarily more rapid, while the general symptoms are more marked and serious. Not uncommonly the patient will offer the signs of true septicemia or even pyemia, developing a suppurating arthritis, peritonitis, or pericarditis, but these intense forms are far less common than those arising after pneumonia. Bilateral tuberculous purulent pleurisy is much less common and is due in most cases to secondary infections with some of the pyogenic bacteria.

The physical signs have nothing special other than the lilateralism of their site. There will be the usual thoracic deformity, but while in the case of a one-sided empyema the deformity is seen at a glance by comparing the two sides, in double empyema, it is, on the contrary, less striking, although in reality more pronounced. Immobility of the thorax on the involved side is another symptom of a pleural collection, while in double empyema the child makes great efforts to draw the air into the lungs, and, therefore, the diaphragm is brought into play. This results in a continued mobilization of the abdominal walls, especially in the epigastric region and merely represents an exaggerated abdominal respiration, the abdominal type of breathing being normal in children.

Mensuration by means of the cirtometer, which gives such valuable diagnostic information in unilateral pleural collections, is naturally useless when the process is bilateral since dilatation is present on both sides. Percussion will give two areas of dullness, usually unequal in extent, the upper curve of which is elliptical with the concavity directed upwards. However, the limits of the dullness may help in deciding whether or not the empyema is total or partial, a matter of manifest importance for the prognosis and treatment. The signs furnished by auscultation in double empyema are the same as in the single form. Nevertheless, it is to be remarked that auscultation of the pleural cavity secondarily involved may be a very delicate matter if the other side has been operated on, on account of the noises resulting from the operative opening, which completely prevent the ear from detecting pathological sounds on the unoperated side.

The signs of pus in double empyema are the same as when only one pleural cavity is involved. Edema of the thoracic walls or fluctuation over the intercostal spaces will hardly, if ever, be encountered. Therefore, the clinician must depend upon the patient's general condition, the facial expression, and temperature chart for making his diagnosis, but it must be frankly admitted that in none too few cases exploratory puncture must be done in order to ascertain the nature of the pleural collection.

INFLAMMATION OF THE BULB OF THE URETHRA.

FOLLOWING upon an anterior gonorrheal urethritis, a localization of the specific organism in the cul-de-sac of the bulb may take place, giving rise to a morbid entity to which has been given the name of bulbitis. The cul-de-sac of the urethral bulb, which is hardly evident in the normal state, may become accentuated, and present characters belonging properly to it under the influence of a chronic anterior urethritis. The bulbar process seems to correspond to a pathological change in the structures already morbidly altered by a chronic inflammatory process of long standing. The normal structure of the inter-urethral sphincter must also be taken into account, for this, from its tonicity and normal contractions, gives the illusion of a dilated portion of the urethra situated directly in front of it. The cul-de-sac of the bulb has no evident physiological use, for the reason that its existence is due to an accidental process. On the contrary, it is the starting point of morbid symptoms which are all the more marked, the more accentuated is the bulbar depression. Microscopically, traces of an old chronic inflammation can often be demonstrated, but with this exception the histological structure hardly differs from that of the rest of the anterior urethra.

Anterior urethritides have a tendency to become localized in the deeper portions on account of the declivity when the subject is lying down, from the action of injections which force the pus backward, from the urine which sojourns at this point, especially if the contraction of the perineal muscles is weak, and lastly, from the slight action exercised by antigonococcic fluids in this region on account of the difficulty of overcoming the sphincteric action and penetrating the bulbar region. Inflammation of the urethral bulb may also be the result of a stricture, especially if it be located in front of the bulbar region, as frequently happens.

The symptoms of inflammation of this portion of

the urethra consist in a peculiar type of discharge, pain on the passage of an exploratory bougie when the olive attains the bulbar region, a localized sensitiveness on direct pressure of the perineum in front of the anus, certain changes in the urine and the jet, and finally negative symptoms in the portions of the urethra just in front of and behind the bulb. Urethral exploration denotes that the source of the pus is exclusively bulbar, if this exploration is conducted with all due care.

Inflammation of the bulb is difficult of cure if a local and direct action on the pathological focus is not obtained, and it is also to be pointed out that the process has a marked tendency to relapse. As to complications of bulbitis, they consist of intra-urethral spasms, epididymitis, posterior urethritis, and inflammation of the vas deferens. These complications are the result of direct extension of the inflammatory process.

BLOOD CHEMISTRY.

THERE is no field in medicine that has been developing more rapidly during the past few years than that of the quantitative determination of the nitrogenous constituents of the blood. Such an examination gives so much more information than a similar determination in the urine that discussion regarding the "nitrogen partition" of the urine, about which we heard so much only a few years ago, has almost entirely ceased. This is due almost entirely to the introduction of methods which require but small quantities of blood and are highly accurate in the determination of very minute quantities of the substances in question. These methods are alike in that they consist in the development of a color reaction after the removal of interfering substances and in the comparison in a colorimeter of the color obtained with that produced in a standard solution containing a known amount of the substance. Methods have been proposed, improved, and modified so rapidly that it has been difficult at times to keep up with their changes, but some of them have still been very time-consuming, and to run through the whole list required a fairly large amount of apparatus, much of which was quite elaborate.

Lately, however, there has appeared from Folin's laboratory a system of blood analysis (O. Folin and H. Wu, *Journal of Biological Chemistry*, 1919, xxxviii, 81) which has simplified the procedure to a marked extent. These authors recommend the use of a new protein precipitant, tungstic acid, and with the filtrate obtained by treating oxalated blood with this reagent they estimate non-protein nitrogen, urea, preformed creatinine, creatine plus creatinine, uric acid, and sugar. It is possible to perform all of these determinations with less than fifty cubic centimeters of the filtrate, which can be obtained from less than ten cubic centimeters of blood. All of the methods have been simplified, so that it would be possible to perform them in a small office laboratory, provided, of course, the necessary solutions were obtained. They are all colorimetric and therefore exceedingly delicate and are stated to be fully as accurate, if not more so, than the methods which have been used up to this time. It is not pretended that this system is the ultimate in blood chemical methods, but it is a great advance and points the way along which future methods will probably be developed. The chemistry of the blood has already been the means of furnishing much valuable information to the clinician, and it is gratifying to see its processes made available to the largest possible number of investigators.

CLINICAL VALUE OF GAREL'S SIGN.

IN 1892, Garel of Lyons described and demonstrated an alleged sign of syphilis connected with dysphagia, prolonged and painful. Pugnat of Geneva, a former pupil of Garel, writes on this sign for the *Journal de médecine et de chirurgie pratiques* for March 25. Largely ignored by the profession as a result partly of the recent revolutionary development of biological tests, the Garel sign has always made good in the writer's experience. To visualize the matter, Pugnat cites the following case: A woman consults him for a sore throat of several weeks' standing; referred to the pharynx, and upon examination he discovers nothing. Suspecting the presence of the disease, he makes special efforts to find a throat lesion. He looks elsewhere for traces of syphilis. Owing to the patient's social standing he dares not interrogate her directly. Indirectly he obtains evidence of failing health for six months past—anemia, asthenia (she is unequal to mounting her horse), headache, history of spots, and only recently of dysphagia. The author, when the patient came under his care, obtained a positive Wassermann and a sight of several lesions of secondary syphilis. The diagnosis representes a triumph over routine procedures, for the medical men first consulted had, after tonics had failed, ordered a trip south for the winter. The author, however, gives the credit to the sign of Garel for making the correct diagnosis. In other words, this persistent dysphagia was motivated in this case by the original presence of a chancre of the tonsil, and even after the lesion had disappeared beyond recognition the subjective sensation persisted. But Garel's sign is not evidence necessarily of chancre of the tonsil, for mucous papules in the same locality—tonsils, fauces, pharynx—often cause the same symptom. And even after the papules disappear the sensation may persist. Finally the same prolonged dysphagia, even in the absence of visible lesions, has been seen in association with tertiary syphilis. The author intimates that a prolonged examination with mirrors should reveal the presence of the lesion. The sign, therefore, is of universal significance, and prolonged dysphagia should always suggest the disease, irrespective of stage, because the throat is a favorite site of both secondary and tertiary lesions, besides being not uncommonly affected in the primary stage. Absence of dysphagia, of course, furnishes no presumption of the absence of syphilis, especially when latent. Jourdanet has also summed up the situation in a statement that prolonged dysphagia referred to the pharynx is almost always suspicious, while Pugnat makes the frequency 95 per cent.

Lymphorrhea Following Operative Wounds of the Lymphatics.

Although lymphorrhea is not extremely infrequent, still it appears to be a rather uncommon complication of surgical wounds of the lymphatics. Nevertheless, it is worthy of the surgeon's attention in the same degree as hemorrhage. Special conditions are required for its production, inasmuch as the operation must be in a region rich in lymphatics, such as the groin, axilla, or base of the neck. The wounded lymphatic vessels must also be of considerable caliber, either a large trunk or else a small trunk in a state of ectasis. Finally, some degenerative change of the vessel walls resulting from the morbid process for which the operation is undertaken prepares the way for the operative lesion to take place. The accident may be discovered at the time of the interference, on account of the profuse discharge of lymph into the field of operation, or the injury to the lymphatics may not be perceived at the time, and will be diagnosed later from the postoperative symptomatology. This consists in local wound symptoms, such as edema along the line of suture, infiltration of the tissues with lymph and sometimes soaking of the dressings. The general symptoms, which vary in degree, are emaciation, great thirst, increased appetite, headache, oliguria, and a small pulse, with occasionally vertigo and lipothyuria. Although in some instances the symptoms may be alarming, lymphorrhagia has not a bad prognosis in general, and in most cases it is good. However, serious complications may arise, due either to the importance of the injured vessel or to the persistency of the flow of lymph and death has been known to ensue. It is, therefore, important to interfere surgically, the means to be employed varying from one case to another. Compression is a good and simple method, but requires to be kept up for some time in order to be effective, and sometimes fails. Compression is indicated in wounds of the small lymphatic trunks or when the lymphorrhea is discovered after the operation; consequently, it will be direct or mediate, according to circumstances. Ligature is an excellent means which, when it is successful, immediately controls the flow of lymph. It is especially applicable in wounds of the lymphatics recognized during operation, but it can be resorted to secondarily when compression fails. Unfortunately, it is not always successful, and also not always possible, in which case forcipressure must be resorted to.

The Spleen and Hepatic Cirrhosis.

Statistics prove that the hepatic cirrhoses are almost always accompanied by a marked hypertrophy of the spleen. The interstitial tissue of the liver when undergoing sclerosis compresses the ramifications of the portal vein, after giving rise to an endophlebitis which in turn brings about a circulatory obstruction of a progressive type from which results an increased intrasplenic pressure with a consequent increase in size of the spleen. But it is also known that splenomegaly may arise when the portal circulation is normal, as for example in hypertrophic biliary cirrhosis. And what is more, the pathological changes in the spleen in cirrhosis are not those occurring in splenic stasis. The hindrance to the flow of blood in the splenic vein produces, by passive congestion, a slight increase in the size of the spleen, which is, however, soon followed by a sclerous atrophy—microsplenia. The latter process is rare and therefore some other reason for the splenic hypertrophy must be sought for, and an important fact to which attention should be called is that in cirrhosis, although no symptom of portal hypertension may be manifest, the spleen is considerably enlarged.

In these cases biliary infection, the cause of the cirrhosis, has been invoked by some who admit that the infectious agent ascending the blood current goes from the liver to the spleen by way of the splenic and portal veins. In these circumstances the autopsy will reveal a soft, diffluent spleen with follicular hyperplasia, while a large number of cell neoformations will be found in the splenic pulp. However, nothing of this nature is habitually found in the spleen of cirrhotics. It is neither a stasis spleen nor a spleen of infection. According to Gauckler the process is a hypertrophic sclerosis of the pulp, that is to say, a reaction of defenses of a hemolytic order, because he was able to observe in the rabbit the same characteristic lesions following injections of hemolysing poisons. Should this theory be accepted, the large spleen of hepatic cirrhosis must be regarded as the outcome of an exaggeration of its hemolytic and leucocytic functions, an exaggeration rendered necessary by the vitiation of the blood resulting from an hepatic affection.

News of the Week.

Death Rates from Influenza.—A report has just been made public by the New York City Health Department which is the result of a questionnaire sent out by Dr. W. H. Guilfoy, register of the records of the department, to various cities requesting statistics on the influenza epidemic. The report shows that the city of Philadelphia, in 1917, had a death rate of 17.10 per 1,000; in 1918, the rate was 25.68. In 1917, 16 out of every 100,000 of the population died of influenza, 138 from lobar pneumonia, 83 from bronchopneumonia; in 1918, 502 out of every 100,000 died from influenza, 339 from lobar pneumonia, and 177 from bronchopneumonia, out of every 100,000 of the population. In Pittsburgh the combined rate from the three causes specified was 306 out of every 100,000, and in 1918 it was 701; for New Orleans the figures were 185 out of every 100,000 in 1917, and in 1918, 750 per 100,000. In Boston the general death rate jumped from 16.46 in 1917 to 22.24 in 1918. The rate from influenza and pneumonia rose from 214 per 100,000 to 815 per 100,000. In San Francisco, the death rate increased from 14.31 in 1917 to 20.08 in 1918; in Buffalo, from 14.22 to 20.06; in Newark, from 15.32 to 19.73; in Washington, from 18.46 to 22.95; in New Orleans, from 19.58 to 25.47; in New Haven, from 16.25 to 20.28; in New York City, from 13.70 to 16.71; in Chicago, from 14.94 to 17.18; in Rochester, from 15.30 to 17.34; in St. Louis, from 14.17 to 16.76. The one exception to a considerable increase in death rate was Detroit, which reports a death rate of 14.35, an increase of only one-tenth of one per cent.

over 1917. The statistics show that the Eastern cities suffered much more severely than did those of the Middle West. On the other hand several of the cities on the Pacific Coast suffered most severely, as Los Angeles and San Francisco.

Promotions in the Medical Reserve Corps of the Navy.—The Navy Department announces the promotion of the following officers of the Medical Corps, Reserve Force, to the rank of Commander; William Seaman Bainbridge, Robert Crier LeConte, William Baret Brinsmade, Stanley Stillman, Eugene Floyd DuBois, Rea Smith, John Chalmers DaCosta, Milton Joseph Rosenau, George Gorgas Ross, Albion Walter Hewlett, Hobart Amory Hare, Robert Battery Greenough, Judson Deland, James Eli Talley, Edward Milton Foote, Paul Adin Lewis, Guy Cochran, Verne Adams Dodd, Edgerton Lafayette Crispin, John Aloysius McGlinn, LeRoy Goddard Crandon, Harold Denman Meeker, Nelson Henry Clark, Halsey DeWolf, Charles W. Moots, George Arnold Matteson, James Taylor Hanan, Francis Joseph Dever, Frank Cousins Gregg, Clifford Elmore Henry, Porter Bruce Brockway, Clinton C. Tyrrell, Frederick Obadiah Williams, Harvey Mitchell Righter, Zachray Thomas Scott, William Curtis Newton, William Henry Areson. This is the first time in the history of the Navy that medical reserve officers have been ranked higher than Lieutenant Commander.

Appropriation Asked for Study of Influenza.—At the recent meeting of the American Medical Association, a resolution was passed by the Section on Industrial Medicine and Surgery asking that Congress should appropriate not less than $1,500,000 to be used under the direction of the United States Public Health Service for the investigation of the causes, modes of transmission, prevention, and cure of influenza, pneumonia, and allied diseases, this sum to be made available to July 1, 1922. We think in big sums these days.

Mississippi County Votes on Eradication of Tuberculosis in Cattle.—What is said to be the first election in the United States to decide whether or not a county should eradicate tuberculosis from its herds of cattle has been ordered to be held in Clay County, Miss., on September 2. The United States Department of Agriculture points out that this election will have much more than local interest, because the election may be the forerunner of many others in other sections of the country. The Department of Agriculture reports that Virginia has a larger percentage of dairy animals which have been tested with tuberculin and found free from tuberculosis than any other state. In the twelve months preceding March 1, 1919, a total of 22,571 cattle were tested in Virginia and only 3.4 per cent. reacted to tuberculin.

Red Cross Starts Life-Saving Course.—The American Red Cross has established a Red Cross Life Saving Corps in order to disseminate a knowledge of improved methods of saving lives after submersion Captain Frederic C. Mills, who is in charge of this activity of the Red Cross Atlantic Division, gave a demonstration of the Shafer prone pressure method of resuscitation used by the Red Cross at Fort Tilden on August 2. All the official life-saving crews at the resorts in the vicinity of New York are being taught this practice.

Vocational Education Board Charged with Inefficiency.—The Association of Disabled Soldiers, Sailors and Marines, organized in June of this year, with headquarters in Philadelphia, finds that hundreds of war cripples throughout the country are registering complaints against the ineffectual results obtained by the Federal Board of Vocational Education. The association charges that the Federal Board has shown a decided unwillingness to cooperate with existing agencies that have offered their facilities freely and generously for training and absorbing into employment disabled soldiers. It is further charged that the Vocational Board has failed to be guided in the administration of its work by the sound scientific principles evolved by other countries that have been recognized as pioneers in vocational reeducation. The Association of Disabled Soldiers, Sailors and Marines points out that according to report of the Federal Board, under date of June 21, 1919, only eleven men have been placed in remunerative employment after completing courses of training. Hundreds of men have complained that they have been compelled to wait from six weeks to six months without pay and to depend upon charity or friends before their cases were finally acted upon by the Board. Many of those trained under the Federal Board Auspices have objected to their pay being reduced by the Board by the amount earned while learning a new trade. This, they claim, is manifestly unfair, since such a method offers no incentive for progress and encourages the employer to exploit the disabled soldier. Another grievance of the association is that it has not learned of a single disabled soldier among the 1,600 employees of the Federal Board, while Australia points proudly to its Repatriation Department, which has 90 per cent. of returned disabled soldiers in its employ. It is claimed that the Federal Board has made contracts with 146,931 men for training, and that of this number only 5,808 have been placed in training. At its present rate of progress it will take the Board a year to place this number in training.

Commissioner Roper Modifies Drug Regulations.—Commissioner Roper, on August 5, issued a statement modifying the rules governing the sale of narcotics in order to permit persons suffering from incurable diseases and aged persons addicted for many years to the use of drugs to make purchases. According to instructions issued to collectors of Internal Revenue, such persons may obtain drugs on prescription by a reputable physician that the drug is necessary to maintain life. Collectors were warned, however, to exercise every reasonable precaution to prevent the aged and infirm from becoming the innocent means whereby unauthorized persons might engage in illicit traffic in narcotics. And so the lay regulation of medical practice goes merrily on.

Dannemora Physicians Absolved by Inquiry.—The prison survey committee of New York State, which investigated the charges of cruelty made against Dr. John Ross and Dr. R. Dexter, superintendent and assistant superintendent of Dannemora State Hospital, reports that its investigation does not sustain the charges of cruelty preferred against

them by Louis Greenspan of New York. The committee finds that there is no basis for the charges, but makes several recommendations for improving conditions in the hospital.

Association of Pharmaceutical Chemists Would Eliminate Heroine.—With a view of correcting the erroneous impression that those engaged in the manufacturing and wholesaling of drugs are opposed to the control of the sale of narcotic drugs, Dr. H. Noonan, president of the American Association of Pharmaceutical Chemists, calls attention to the following resolution which the association passed at its last meeting in Atlantic City, during the week of June 2, 1919: "Resolved, That the American Association of Pharmaceutical Chemists reiterates its resolution, adopted two years ago, that the narcotic drug heroine be eliminated from all medicinal preparations, and that legislation (Federal and State) be enacted to require such elimination. Dr. Noonan states further that those legitimately engaged in the manufacture and sale of drugs are heartily in sympathy with the efforts being made to control the narcotic drug situation, and desire to lend effective cooperation to those charged with the responsibility of correcting the evil.

New Home for Beth David Hospital.—The Beth David Hospital, Lexington Avenue and 113th Street, New York, has completed plans for the erection of a seven-story building on its present site. The institution now has accommodations for fifty patients, while the new hospital will be able to care for 150 patients, and will have increased dispensary facilities. A drive will be begun in September to raise $100,000 needed for the new building. Work on the new structure is to begin soon.

Dr. Simon Flexner of the Rockfeller Institute for Medical Research has been elected a Fellow of the Royal Society of London.

Dr. Howard Fox has returned from active service in France, and has resumed his practice at 616 Madison Avenue, New York.

Dr. Etta Grey of Los Angeles has sailed on the steamship *Chicago* to establish medical relief work in and near Belgrade under the auspices of the American Women's Hospitals.

Capt. Joseph E. Campbell of Patterson, N. J., who recently returned after almost two years' service with the United States armies in France and Germany, has been awarded the Croix de Guerre, with palm, by the French Government for conspicuous gallantry during the battle of Cantigny.

Major James O. Tryon, field director of the American Red Cross at General Hospital No. 41, Fox Hills, Staten Island, has resigned to return to his professional duties.

Grippe in Italy Worse than War.—According to statistics published by the *Secolo,* Italy, during 1918, had 800,000 deaths caused by influenza, which was 60 per cent. more deaths than were caused by the whole war.

New Wing to Long Branch Hospital.—A $150,000 addition to the Monmouth Memorial Hospital, Long Branch, N. J., was dedicated with appropriate ceremonies on July 19. This new wing to the hospital is the gift of Mr. and Mrs. Charles A. Wimpfheimer of New York City, in memory of their son, Private Jacques Wimpfheimer, who died in the service in a Hoboken hospital a year ago last winter. The new wing doubles the present capacity of the hospital.

Bellevue Hospital Ship Sunk.—The barge *Huddleston,* used as an adjunct to Bellevue Hospital for the accommodation of convalescent women and invalid children, was rammed by a tug at her pier, Corlears Street and East River, and sunk on August 1. No patients were aboard at the time. It is believed that the vessel can easily be raised.

New York Records Lowest City Mortality.—The death rate for New York City for the week ending July 26 is the lowest on record for any week during any year since the Department of Health was organized in 1866. The rate was 8.87 per 1,000 population, as against a rate of 11.21 during the corresponding week of 1918. The next lowest death rate was that for the week ending June 21 of this year, which was 9.10, and the next lowest was that for the week ending July 19, which was 9.16. In the past the high death rate during the month of July has been from heat stroke and from diarrheal diseases among children. As a rule, plenty of rain in June and July are accompanied by a low death rate from diarrheal disease among children and from heat stroke. During the week of July 26 there were 92 deaths from diarrheal disease among children under five years of age, against 128 similar deaths for the corresponding week of last year. Many other diseases showed a falling off in mortality, especially chronic organic diseases of the heart. The death rate for the first thirty-two weeks of 1919 was 14.48, as against a rate of 14.22 for the corresponding week of 1918. The infant mortality rate since January 1, 1919, to date, was 86 per 1,000 living births, exactly the same figure as for the corresponding period of 1918.

Seized Drugs Go to Army and Navy.—A shipment of narcotic drugs valued at $200,000, including heroin, cocaine, morphine and opium, seized in New York during recent raids by Federal agents against illegal traffickers, has been sent from the office of the Internal Revenue agent at the Customs House to the Commissioner of Internal Revenue at Washington. This consignment will be diverted to army and navy hospitals for medicinal use. More drugs have been confiscated in New York during the past six months than during any previous six months' period.

Typhoid Fever in New York.—During the second quarter of this year there have been 99 cases of typhoid fever reported, as against 268 cases during the corresponding quarter of 1918. During the quarter 13 cases were reported as typhoid fever which were subsequently dropped as "no cases," having been erroneously diagnosed and reported as such. During the corresponding period of 1918, 42 cases were reported and dropped. During this quarter 89 per cent. of the true cases reported were confirmed by laboratory examination. Twenty deaths from typhoid fever were reported during the second quarter, as compared to 29 during the corresponding period of 1918. The source of infection was traced in only 24 per cent. of the reported cases this quarter, as contrasted with 40 per cent. traced in the corresponding period of last year. This is accounted for by the fact that the cases this year

have been so widely scattered that it has been exceedingly difficult to trace their source.

Obituary Notes.—Dr. Otis Johnston, a graduate of the Chaddock School of Medicine, Quincy, Ill., in 1889, died suddenly of heart disease, in his office in Quincy, on July 21, aged 52 years.

Dr. John Howard Sherman, a graduate of Castleton Medical College, Castleton, Vt., in 1857, died at his home in South Boston, on August 2, aged 89 years. Dr. Sherman had practised in Nantucket, Middleboro, San Francisco, and Lynn, before coming to South Boston. He served as president of the Homeopathic State Medical Society of Massachusetts, the State Surgical Society, and the Boston Homeopathic Society. He was an honorary member of the Maine State Homeopathic Society.

Dr. Henry Zimmerman, an officer in the Medical Corps of the United States Army during the war, died suddenly in Springfield, Mass., on August 7.

Dr. William Muir Allen, for many years a practitioner of Louisville, Ky., died of pneumonia at the home of a relative in that city, on July 29, at the age of 90 years. He was in the Kentucky Legislature in 1862, and later was a candidate for the United States Senate.

Dr. Albert D. Turner of Binghamton, N. Y., died in a local hospital following an attempt to perform an operation on himself, on August 3, aged 80 years.

Correspondence.

DRUG ADDICTS AND THE TUBERCULOUS IN ONE INSTITUTION.

To the Editor of the Medical Record:

Sir:—There has been a great deal of agitation of late concerning the cure of drug addicts. Because of the rejection by the city government of the Rockefeller Foundation offer of its removable hospital buildings and the City Island citizens' protest against the use of the buildings of the Pelham Bay naval training station for the purpose of treating New York City's drug addicts, the Sea View Hospital for the tuberculous on Staten Island has been turned over to Health Commissioner Copeland for that purpose. An amendment to the sanitary code designating drug addiction as a "pestilential disease" has been adopted and thus the Department of Health legally takes the medical control of patients chronically addicted to the use of opium, morphine, cocaine, and its allied products.

As an antituberculosis worker in this city for wellnigh a quarter of a century, I beg leave to enter as strong a protest as I possibly can against the utilization of Sea View Hospital on Staten Island for the treatment of drug addicts. Here is the finest building of its kind in the world, having been erected at the cost of $5,000,000 for the exclusive use of patients suffering from tuberculosis, especially designed and equipped for this purpose. It is the only institution which not only takes care of patients afflicted with tuberculosis of the lungs in all stages of the disease, but also of orthopedic cases and of tuberculous maternity cases. All other institutions are limited either to adults or to children, to joint or lung diseases only, or, again, only to cases in the first, second, or last stages of the disease. Sea View has an enviable reputation because of its admirable work and excellent management. It is visited by physicians from all over the United States and Europe, who pronounce it the best of its kind in the world. And now it has been decided to turn over this valuable plant to the use of drug addicts, the tuberculous patients to be turned out and distributed among other institutions. It has been said that of the 700 patients now at Sea View, only those in the advanced stages, that is to say, whose conditions will not permit removal, are to remain there. One of the immediate results of limiting Sea View to advanced cases will be that our tuberculosis clinics, already hampered by the work for drug addicts, will be at a loss where to send maternity and orthopedic cases.

Any one, be he physician or layman, who visits Sea View Hospital, will find there hundreds of patients looking and doing well, and as happy and contented as can be, considering the disease they are afflicted with. By receiving the advanced cases from the crowded tenement districts, Sea View Hospital suppresses centers of infection, renders the hopeless patient comfortable and lessens the sufferings by judicious symptomatic treatment. It is a physical impossibility to send all the tuberculous patients of a great city to distant mountain resorts, and when the atmospheric conditions which the average patient has in his tenement home are compared with those that await him at Sea View Hospital on Staten Island, one must admit a decided climatic advantage.

I am convinced that our city administration made an unfortunate mistake in not accepting the Rockefeller Foundation offer of its removable buildings to be placed at Warwick or some other locality where a special hospital for the treatment of drug addicts could be established. To cure a patient of his addiction to opiates should not and does not take many months, and if our laws against the illicit sale of narcotics are enforced and Dr. Copeland succeeds in curing all addicts in the city, there should be no need for such permanent and costly buildings as constitute the Staten Island institution.

Sea View Hospital has been chosen for the treatment of drug addicts because of its thousand beds only about 700 are occupied, but all public tuberculosis institutions are less frequented in summer than in winter, and, compared with the Metropolitan Hospital for Consumptives, Sea View shows a very good summer record. The following are the exact statistics of the five municipal tuberculosis hospitals: Riverside Hospital, on North Brother Island, has 504 beds, of which 117 are occupied; Kingston Avenue Hospital, Brooklyn, has 165 beds, of which 12 are occupied; the Municipal Tuberculosis Sanatorium, at Otisville, has 599 beds, of which 515 are occupied; the Metropolitan Hospital, on Blackwell's Island, has 814 beds, of which 255 are occupied; and the Sea View Hospital has 1008 beds, of which 675 are occupied.

I hope serious reflection will convince the city authorities that the present plan to take Sea View Hospital from the tuberculous and make it a hospital for drug addicts exclusively, or even in combination with a hospital for the hopelessly advanced cases, is a serious mistake. New York City has an enviable reputation as a pioneer in the ad-

ministrative control of tuberculosis. To do away with Sea View Hospital as a model institution for the treatment and care of the worthy consumptive poor, for which it was originally intended, would be a backward step in the antituberculosis movement. The greatest city in the Western hemisphere can ill afford to give such an example to the civilized world.

S. ADOLPHUS KNOPF, M.D.

NEW YORK.

COSMETIC SURGERY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—These are times of reconstruction not only of governments and economic conditions but—of faces. Very interesting work has been done—as we all know from exhibits, illustrated articles and even novels—with the aim of making the war-scarred soldier not only presentable but even handsome. He is provided with a new nose or a new upper lip as required, and special pains are taken to make his new nose shapely and to take the graft for his upper lip from the top of his head so that he may not be deprived of the ornament of a mustache!

Inevitably our thoughts revert to a few years ago before the war when cosmetic surgery was considered rather a shady business. Physicians were then decidedly chary of doing operative work for purely esthetic reasons. Although besieged by men and women who felt that their happiness in life depended on the alteration of some offending feature, they discouraged them or even refused point blank to operate, with the result that quack institutions throve on the treatment of facial defects. Such institutions have been known to approach a surgeon of good standing and offer him large sums of money to operate anonymously on patients furnished by them, probably not realizing that if he so desired he might spend his entire time performing the same operations on patients coming to him direct.

Possibly on account of the disrepute in which surgery for cosmetic purposes was held before the war, its methods were shrouded in mystery and its procedures were supposed to be fraught with tremendous difficulties. Fortunately, the publicity connected with the recent reconstruction work has changed all this. The mystery has vanished and the tremendous difficulties so much talked about proved practically non-existent.

A propos of the latter, let us take an example from civil life and suppose that a woman with a large nose of the Hebraic type comes to have the hump removed from the offending feature. This is not a difficult thing to do—not nearly so difficult as building up a war-shattered nose. Any man who can remove cartilage from a nose can go a little farther and scrape a hump off it. Moreover, we make bold to affirm that when the hump is off no harm is done. On the contrary, the woman is happy, the rhinolaryngologist is happy, and presumably society at large is happy that an ugly nose has been replaced by a handsome one.

It is our hope, then, that the influence of the facial reconstruction work of the war, which has banished the mystery and the odium of cosmetic surgery and has improved its methods, will be sufficiently far-reaching to give the civil population in peace times the same benefits enjoyed by the soldier in times of war. Cosmetic surgery, we feel, should at this auspicious moment be taken once for all out of the hands of charlatans and quacks and given a legitimate status in the profession.

SEYMOUR OPPENHEIMER, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 18, 1919.

The British Federation of Medical and Allied Societies.—The Medical Parliamentary Committee has taken a distinct step forward and has embarked definitely and practically upon a career that should mean much if the movement is cordially supported, but which can mean nothing at all if the energetic adherence which is promised does not materialize in deeds. The position may be summarized as follows: In October of last year at a mass meeting of the profession Dr. Christopher Addison, the Minister of Reconstruction and now holding a new portfolio as Minister of Health, moved and carried a successful resolution to the effect that in the interests of national health it was essential that the considered views of the medical profession should be voiced by representative medical men in the House of Commons. This resolution sufficiently proves that the first idea of the Medical Parliamentary Committee was to elect to Parliament persons (themselves or others) who, being medical men, should in the House of Commons be able to enlighten the legislature on the medical bearings of any new bills and the medical reasons for or against any suggested amendment of the law. But it was made abundantly clear at that first meeting that the Medical Parliamentary Committee could not assure such a programme, if only because medical men cannot be elected to the House of Commons as such, but only if they comand the political support of their neighbors. As medical members of Parliament have always proposed as far as possible to contract out of party politics, only a very few doctors could ever hope to be elected. If they were good doctors they were so busy professionally that they could not follow party politics, and, conversely, if they were not good doctors the medical profession could not consider that their accidental possession of degrees and diplomas fitted them in any way to represent the calling of medicine in Parliament. It became clear that the Medical Parliamentary Committee must do much more than move for an increased number of medical legislators if it was to be of practical use. During the next six months therefore a temporary executive committee sitting under the chairmanship of Sir W. Watson Cheyne set about formulating a policy by which the Medical Parliamentary Committee could obtain for medicine a voice in the councils of the nation. Now and again this committee met the constituency to which it had promised to report, when its various steps received drastic criticism, sometimes useful and sometimes merely stultifying. The committee stuck to its work; and they secured from the British Medical Association a neutral admission that while the association, representing half the medical profession of the Kingdom, could not admit that it was not the proper body to effect exactly that at which the Medical Parliamentary Committee was aiming, still

it would like to remain informed of all the proceedings, when it would bring the question of its own adherence before its governing body. As far as the British Medical Association is concerned, the position remains the same, but in the meantime a very large number of medical and allied societies have come to agreement upon a line of procedure, and incidentally so many representatives of these societies are members of the British Medical Association that indirectly that association is now concerned with the success of the movement.

Last week the temporary executive of the Medical Parliamentary Committee called a meeting of no less than 47 societies which had promised support, and to the representatives of these bodies the new programme was presented in the form of a report. The report ran as follows: In pursuance of the resolutions passed at the conference on May 2, 1919, the provisional sub-committee have to report: (1) That the office of the committee has been temporarily established at 20, Hanover-square, London, W.1. (2) That the sub-committee has met on five occasions for the purpose of deliberation and conduct of business. The following resolutions, as recorded in the minutes of these meetings, have been passed: (*a*) The appointment of a provisional chairman in the place of Sir William Watson Cheyne, resigned. This office has been offered to, and has been accepted by, Sir Malcolm Morris, K.C.V.O. (*b*) The appointment of a provisional organizing secretary. This office has been offered to, and has been accepted by, Dr. N. Howard Mummery, who has offered to act in an honorary capacity until the conference called for July 11, 1919. (3) That the necessary estimated annual and preliminary expenditure is respectively £1,826 and £192. £2,018 in all. (4) That in the opinion of the provisional sub-committee the time has now been reached when it is essential to further expansion and increased activities that: (i) The committee should establish a federation under the title of "The British Federation of Medical and Allied Societies" to carry on the work commenced by the Medical Parliamentary Committee. Only thus can it acquire the financial basis necessary to its further existence. (ii) That such Federation should form itself into an incorporated association, limited by guarantee and not having a share capital, under the Companies' Acts, 1908-1917. That it be registered under the Board of Trade (Section 26) with limited liability, without the word "Limited" after its name, but with the word "Incorporated" added. In this form it is expressly laid down that it cannot be considered a "trade union." That it be registered under the title of "The British Federation of Medical and Allied Societies (Inc.) late Medical Parliamentary Committee. (5) That the representatives of the affiliated and allied bodies and the coopted members shall form the Council of the Federation. (6) That an Executive Committee be elected to carry out the business of the Federation, with power to engage the services of the necessary officers and servants on the salaried list, obtain the necessary permanent officer of the Federation, with power to appoint sub-committees, and to incur the necessary preliminary expenses.

All these sections of the report were adopted by the meeting in substance, discussion here and there clearing up what seemed to be doubtful points. The resolutions referred to in the paragraph as having been passed at a previous conference show that the story of the movement is one of continuity. I quote the first resolution to show this: 1. That a permanent Medical Parliamentary Committee be formed for the purpose of: (*a*) supplying early information of the trend of opinion on health questions; (*b*) supplying early information of impending legislation to the constituent bodies; (*c*) facilitating communication between the several bodies affected by the proposed legislation; and (*d*) assisting in increasing medical representation in Parliament. The change of title was justified though a little regretted by the fact (1) that it seemed to give too much prominence to what had become now a secondary issue, namely the election of medical men to Parliament, and (2) by using the word federation the procedure adopted by other national group movements was followed. It was especially noted that the adjective "British" covers the interests of Ireland and Overseas Dominions.

The seventh section of the report, dealing in detail with the finance, was held over for future consideration. The estimate of income required was not challenged, but the scheme for raising it presented difficulties which could not be dealt with at a public meeting. Many of the representatives of the 47 societies present did not feel themselves in a position to pledge their bodies to any definite pecuniary liabilities. It remained then only to elect the principal officers, the Council, and the Executive Committee. The following are the officers elected: *Chairman*, Sir Malcolm Morris; *Vice-chairmen*, Dr. Arthur Latham, Dr. E. H. M. Stancomb; *Hon. Treasurers*, Sir Thomas Horder, Dr. J. F. Gordon Dill; *Hon. Secretary*, Dr. Charles Buttar.

It was agreed that of the Council, numbering 53, and the Executive Committee, numbering 20, a certain proportion only should be consulting physicians or surgeons. The full Council is constituted by the election of the Council of the Medical Parliamentary Committee, reinforced by the ten coopted members whose names are given above, of whom two only may be in consulting medical practice. A guarantee fund approaching £2,000 was obtained at the meeting when the scheme was adopted, so that for one year the new Federation should be able to devote itself to making good, free of pecuniary responsibility.

The Medical Insurance Agency.—The report of this semi-philanthropic organization for the year 1918-1919 is eminently satisfactory. Insurance—life, house, fire, and motor car policies in particular—has boomed, and the rebates made to medical men through the agency have been considerable. The agency out of profits was able also to distribute just over £1,000 during the year to medical charities.

Archivos de Biologia de Sao Paulo.—Several numbers of this new periodical have reached us. The subject-matter appears to comprise all maladies which can be reached by biological products as well as biological diagnostic resources. Products of any kind which are intended for intravenous medication, like tartar emetic, have a careful description of technique. The work appears to revolve about the activities of the Laboratorio Paulista de Biologia, which we take to be a government enterprise.

1. War Neuroses as Observed in Army Neurological Hospitals at the Front.—John H. W. Rhein observes that the war neuroses seen among the American forces present some features differing to a certain extent from those seen in the armies of England and France. He divides the patients coming into neurological hospitals at the front for the most part into: 1. Those in whom there have already developed hysterical phenomena, such as aphonia, deafness, blindness, palsies of the limbs, amnesias, and confusional mental states. 2. Those who have well-defined anxiety states. 3. Neurasthenias. 4. Psychasthenias. 5. Those who are best described as examples of hypermotivity. Besides these there are a small number of soldiers suffering from actual psychoses, a few from organic nervous diseases, epilepsy, mental deficiency, and, finally, a number of cases showing transient symptoms which have the coloring of psychoses from which the patients speedily recover and follow a similar course to the war neuroses generally. The states described by the soldier as periods of unconsciousness, the writer views as hysterical phenomena, pure and simple. They consist of faints, confused states, or amnesias. There is also a group of cases which show practically no symptoms after a few days' rest except a mental attitude toward line work and a history of definite, unnerving reaction to shelling. These the writer looks upon as instances of what he has termed hypermotivity. Soldiers belonging to this class are unable to carry on under shell fire; they feel weak, dizzy, tremble, cry, and are afraid. Upon the arrival of such a patient at the hospital he presents few symptoms. Over 60 per cent. of the patients coming into the neurological hospital were restored within an average of ten to fourteen days to a state of apparent nervous stability. The method employed to bring about these results consisted in explaining to the soldier in the receiving ward, before he was actually admitted to the hospital, the exact nature of his condition, and in reassuring him as to the prognosis. Almost immediately there was a relaxation of tension from which nearly all the patients suffered, and the soldier experienced an enormous relief from the anxiety of the situation in which he found himself. He was bathed, fed, and put to bed, whereupon he usually fell into a profound slumber which lasted from thirty-six to forty-eight hours. He was then examined by the war psychiatrist, who explained to him the mechanism of the condition and treated him by suggestion. The patient was next interviewed by the commanding officer, who went over his history, and again explained the nature of his symptoms in a way that robbed them of horror and mystery which surrounded them, and he also gave reassuring suggestions. After a brief rest period, usually three to five days, all the patients were put on a schedule consisting of rest periods, graduated exercises, hikes, periods of recreation, games, and group singing, which occupied the entire day. In twelve to fourteen days from 60 to 70 per cent. were again fit for line duty. In the base hospital, however, one found a different picture. Hysterical manifestations were observed, stammering spread through a ward, mutism appeared, some paralyses, more rarely gait disturbances, and amnesias appeared. This made it seem that these men had acquired a state of suggestibility which permitted a return to a fairly normal state rapidly when properly treated, and, on the contrary, if allowed to be exposed to contagion and pernicious suggestion, the development of hysterical phenomena and anxiety states was favored. While the writer believes that it goes without saying that a man with a previous history of unstable nervous system is more susceptible to the experiences of battle there were many who presented symptoms in whom there was no such history. They acquired in a short time a state of instability which in civil life would take months or years to develop. In 320 histories, 174 were negative as to previous nervous manifestation. In 146 there was a history of nervousness, nervous breakdown, nervous temperament, chorea, fear of the sight of blood, phobias, traumatic neurasthenia, bed-wetting, sunstroke, delinquency, dizzy and fainting spells, hysteria, and drug addiction. Previous occupation played some part in rendering a person susceptible to the influences causing neuroses. In 327 case histories there were 46 farmers, 38 clerks, 30 laborers, 85 skilled laborers of various types, and four physicians. Family predisposition was observed in a certain number of cases. It was negative in 195 cases, and positive in 137 as to insanity, cancer, tuberculosis, or nervous manifestation in father, mother, sister, or brother. In a small number of cases there was a psychotic reaction resembling dementia praecox. The reason one found this variety of reactions to similar experiences offers an interesting field of speculation.

4. Bacteriology of the Recent Pandemic of Influenza and Complicating Infections.—William H. Park states that to identify a microorganism as the cause of a widespread epidemic, the germ must be capable of producing the type of disease under investigation; it must be present in the advancing area in all cases at the beginning of the infection, and in any outbreak it must have the same characteristics when freshly isolated from different patients. The repeated transfer of a pathogenic germ from patient to patient allows the most characteristic forms to increase, so that until an epidemic is on the wane it will be found that isolations from different cases from different localities are practically identical. Even well trained bacteriologists frequently fail to realize that an epidemic strain is alike everywhere in cases belonging to the epidemic. The writer reviews results of recent investigations which furnish convincing evidence that the difficulty of being certain that any suspected cases are due to the pandemic virus is increasing. There is no proof that any one germ is present in all cases. The influenza bacillus has the lead among the possibilities, partly because of its historical position and partly because, as it requires much training to isolate it from a mixture of other bacteria, the thought remains in the minds of many that the failure to obtain it in some outbreaks is due, not to its absence, but to lack of training in the bacteriologist seeking it. If isolations from a number of cases proved to have identical characteristics, the probability that the influenza bacillus was the cause of the epidemic would be great, while if many strains were found it would be slight. Williams and the writer decided, therefore, to test the immunological reactions of isolations from more than 100 cases. They also tested great numbers of isolations from a few cases. It was found that from the same case either all or the great majority of isolations were identical in their reactions, but that the majority of the isolations from different cases differed from each other either completely or essentially. The results seemed to show that the in-

fluenza bacilli, like pneumococci, have gradually through the years altered on the mucous membranes of healthy carriers into many strains which, while having many essential characteristics, are still different in their susceptibility to specific immune substances and perhaps in other reactions. In order to test the stability of the strains several strains were passed through a series of animals, and others were grown for many generations on different mediums, but without causing any appreciable change. An interesting observation made during this work was that when a plate culture is made from material containing several strains, apparently pure colonies will not infrequently yield two different strains. The resultant mixed culture will agglutinate with each of the two serums. Even further plating may fail to separate them. An important point was whether the infecting strain could be depended on to produce the major part of the organisms in a case. If it did, isolations from the plates made from nasopharyngeal cultures could be considered as belonging to the infecting strain. In this connection some of their laboratory findings were instructive. One of the workers developed an acute bronchitis. Cultures revealed abundant influenza bacilli. Fifty fishings of colonies from the plates were found on testing to give 49 identical organisms, and one that belonged to a different strain. Another bacteriologist, by accident, received an infection from a freshly isolated culture. About 30 colonies were fished from the plate culture, and all proved to have identical characteristics. Other tests gave the same results. It seemed right, therefore, to assume that the infecting strain was in great excess during an infection and that in nearly every case the colony tested will represent the infecting strain, and that the proof that patients are infected by different strains indicates almost certainly that bacilli were present before and that some other virus created conditions permitting the latent bacilli to attack the tissues. In the opinion of the writer these results appear to throw the influenza bacilli in the cases studied clearly into the class of secondary invaders and to indicate that the microorganism causing this epidemic has not yet been identified.

3. The Results to Be Expected from Antenatal Care.—Eardley Holland expresses the conviction that both the medical profession and the lay public have engaged in so impetuous a pursuit of antenatal work that they have not paused to consider what results they are really justified in expecting from it. He believes the time has come to balance accounts and find out whether results justify the effort expended in the work. He urges the need of keeping records, on a standardized system, at every large maternity center. From the records of pregnancy, of labor, and of the year subsequent to labor, both for the mother and the infant, we should be able to state the profits of the enterprise. The writer cites statistics showing that the reduction of the dead birthrate by one-half, which would be a remarkable achievement, would raise the living birthrate by only a fraction of 1 per cent. He shows that out of 50 per cent. of fetal deaths that are theoretically preventable about 20 per cent., of which three-quarters are due to syphilis, could be prevented by antenatal methods alone. About 12 per cent. depend for their prevention on combined antenatal and intranatal methods, and 20 per cent. on intranatal methods alone. The point to be emphasized is, therefore, the immense importance, in the prevention of fetal death, of the management of the intranatal period. More fetuses can be saved by improved intranatal care than by antenatal care. While we must not abate by one jot our enthusiasm for antenatal work, yet the importance of the intranatal period and the necessity of getting a better standard of midwifery must be recognized much more than it is at present. This conclusion is forced upon us when we realize that the majority of dead fetuses have met their death in the intranatal period, and that many cases of intranatal fetal death occur from causes beyond the control of antenatal care, and that antenatal care itself depends on intranatal skill for its successful issue.

2. Fractured Noses.—Douglas H. Stewart calls attention to a very natural, though mistaken, idea that a broken nose is caved in much as a gable roof might be caved in by too heavy weights upon its ridgepole. This would mean that the nasal bones would be driven in, would be rotated inward, or might even be overlapped at their anterior margins, or it would mean that the bones would spread at their rear edges and would jam together at their forward edges. As a matter of fact, the nasal bones when driven in slip off the articular surfaces of the maxillary processes and slip into the nostril inside of the maxillary processes, with their rear edges driven together, with the whole bone rotated outwards, and with the front edges separated or spread. In view of these conditions the obtaining of a fair result demands both the elevation and also a rotation of the bones inwards, so that the anterior margins once more return to their former contact. Usually the elevation of the bones is readily accomplished by the introduction into the nostril of a lead pencil or similar article, properly cushioned by absorbent cotton, and then pinching the bones together or rotating them inward by the operator's fingers. If the bones do not stay in place the pin part of a rather large safety pin may be driven through the notch in the outer extremity of the lower border of the nasal bone, through the whole thickness of the nose, passing across both nostrils, and when it projects from both sides the pin may be locked, thus giving control of the nose. By introducing little pieces of wooden tongue depressors wrapped in cotton beneath the free ends of the safety pin, the bones may be wedged into position and the whole retained by adhesive plaster. If there is a suspicion that the nostril is blocked, an attempt to pass a cotton wrapped applicator should be made. If such a block is caused by the dislocation of the septum it may be corrected by employing the operator's finger as a wedge, and kept in place by means of a malleable splint. For this purpose Kyle's splints are excellent, or a hairpin wrapped in cotton, well vaselined, is useful in an emergency. A little ingenuity usually enables the operator to apply the splints in such a way as to leave one nostril free, thus adding greatly to the comfort of the patient.

2. The Influence of the War on Surgery. Civil and Military.—George E. Armstrong notes that it has been said that war surgery is something different from civil surgery; that war surgery has been of a rough and ready kind. Speaking from his experience in the present war, this view is erroneous, and can only be held by those not fortunate enough to have seen any service overseas. The principles of war surgery are those developed, taught and practised by the masters during peace. They are the same in Flanders Fields as in the Dutch, Swiss, or American civil hospital. One might say that during the war the work assumed more the character of acute surgery, and yet at the base there is, sad to say, gradually accumulating a mass of chronic surgery that will call for all our energy and resources.

Our pre-war ideas of the treatment of wounds of the soft and hard tissues have been modified. Changes that are indeed radical have occurred in our estimate of the value of antiseptics and drainage. Occasion has been offered to acquire in a week a wider experience and a greater knowledge than could have been gained in a liftime in civil surgery.

No conditions or surroundings have come under Armstrong's notice that have more quickly and correctly established a man's value as a surgeon, than the work of the casualty clearing station. In these stations he is not working alone, but side by side with his peers. The consultant of the district has him under his eye. He must deliver the goods or stand by. The character of the work is estimated by three standards: Mortality, military usefulness, and post bellum value as a citizen. A feature of the work of the Army Medical Corps during the war has been the appreciation of the advantages of specialization in medical and surgical work. Indeed, Armstrong says that he makes it stronger and states that the war has demonstrated the necessity of specialization in war medicine and surgery. The point is made clearer by reference to one or two specific conditions: The treatment of fractures of the femur is an example of the improvement in and results obtained by specialization. Until General Sir Robert Jones was called upon to bring order out of chaos the results from these fractures were lamentable.

With reference to the operative treatment of intra-abdominal wounds, he draws attention to the fact that the mortality has been unquestionably lowered. It is still high, probably not much below 50 per cent., but even that means many lives saved. The war has brought into closer daily association the surgeon and the scientific workers in the scientific departments closely allied with practical medicine and surgery. Chemists, physiologists, bacteriologists, biologists, and pathologists have been brought into intimate association with the problems of the bedside. Many have for a long time felt that in our medical schools and hospitals there has been too great a dissociation between the primaries and finals, between the workers and teachers in the scientific and practical subjects. It must always be remembered that the medical work of the war has been performed by the medical profession, and after the war they will doff their military dress and resume civilian practice enriched by their varied experiences. The lessons learned during the war will be applied after the war.

Among the questions suggested by the experiences of the medical profession gained during the war, Armstrong believes that one of the most important and far-reaching will be the subject of medical education. What the more immediate changes may be it is difficult to predict, but that both undergraduate and graduate studies will be differentiated more in the future than in the past is highly probable. The same factory cannot turn out Ford and Rolls-Royce cars, nor can the same school turn out general practitioners, physiologists, biologists, and chemists with economy of time to all. The undergraduate teaching best adapted to one intending to devote his life to preventive medicine is not necessarily the best education for the man preparing for curative medicine.

There is another question arising out of the study of the work by the Army Medical Service, and that is its influence on the personnel. Specialization has been a blessing to the soldier; it has narrowed the vision and perspective of the surgeon. After the war these men cannot occupy their whole time working in such a restricted field. Even in the greatest surgical centers there will not be a sufficient number of broken femurs, or nerve wounds, or mutilations of the face to absorb all the time and energy of a surgeon. Re-education will be needed. Many men have worked in hospital wards doing routine dressings, some have been engaged as combatants, others in administrative work; very few have seen much of both medicine and surgery. Before they return to their homes and resume practice they should be afforded an opportunity of brushing up. The better class of men will seek such opportunities, others should be encouraged to find them.

Revulsives for Hastening the Appearance of Exanthems.—D'Oelschnitz refers to the use of the hot bath, sinapisms and other old resources sometimes employed to hasten a diagnosis in case of infectious exanthems. As a result of conditions growing out of warfare he was compelled as early as 1914 to draw on such resources in connection with early diagnosis, isolation and wholesale prophylaxis. Of various provocatives tested none gave such good service as dry cups, by means of which blood was mechanically determined to the surface. All of the contagious exanthematous diseases were represented and the cups were applied to the surfaces of predilection. In the case of measles there is an eruption which can be brought out at times by mustard and by use of cups in the favorable areas a similar result was obtained. The technique is very simple, and a rubber bulb, or better, a suction appartus having a pump is applied in situ. Too much suction defeats the end in view. A mild hyperemia should be the aim. Measles is the disease in which the author has been chiefly concerned, and when the test in a suspect is negative it apparently possesses value. The positive find is less valuable because the cup may cause a type of reflex akin to dermographism which, however, should not be difficult for an expert to exclude. If this early eruption is obtained but not followed by the exanthem one may of course speak of an abortive case. The test is, of course, to be used only in the stages of invasion and incubation, but when applied for diagnostic purposes after the rash is out, might possess some value, especially in morbilliform eruptions from alimentary toxemia, etc. In scarlatina the use of the cup gives some positive phenomena such as hemorrhagic puncta and lesions which desquamate, but in the absence of colored plates it is not easy to visualize the finds in either of the eruptions. In practice at the author's hands the results speak well for the method, the tendency to hemorrhage being of value in both measles and scarlatina. No figures or percentages are submitted to show the exact worth of the method, but by reason of its simplicity and harmlessness it is deserving of routine use not only in eruptive fevers, but in other types of dermatosis.

Results of Ablation of the Tonsils in Rheumatismal Diseases.—Nordlund, having extirpated the tonsils of thirty subjects for acute amygdalitis, of which number eighteen were complicated by polyarthritis of a relapsing type and twelve with nephritis, kept the cases under observation for an average of several years. In most of the cases of relapsing joint disease the results were excellent, and as a general proposition this resource will prove curative in this condition. In addition to disposing of the joint lesions the patients also showed general improvement, including defervescence in febrile cases. In certain cases, however, the improvement was not apparent until after one or two weeks. Hence the therapeutic status of the treatment is a cutting short of the course of the disease in question, even when this is present in the acute form. The same resource is of equal value if the disease is chronic at the time of operation. In acute hemorrhagic nephritis following upon angina ablation of the tonsils was distinctly curative.—*Hygiea.*

Book Reviews.

AIDS TO SURGERY. By JOSEPH CUNNING, M.B., B.S., F.R.C.S. (Eng.), Surgeon to the Royal Free Hospital, late Surgeon to the Cancer Hospital, late Surgeon to the Victoria Hospital for Children, Consulting Surgeon to the Thames Ditton Cottage Hospital; and CECIL A. JOLL, M.S. (Lond.), F.R.C.S. (Eng.), Assistant Surgeon to the Royal Free Hospital. Fourth edition. Price, $2.00. New York: William Wood and Company, 1919.

PROPERLY used (that is, as an aid and not as a textbook), this little volume should prove of great service to the student. It is based on the standard work of Rose and Carless, but its value is by no means limited to students of that book. This new edition is brought up to date and includes many of the advances recently made in military surgery.

SURGICAL ASPECTS OF TYPHOID AND PARATYPHOID FEVERS. Founded on the Hunterian Lecture for 1917. Amplified and Revised. By A. E. WEBB-JOHNSON, D.S.O., M.B., Ch.B. (Vict.), F.R.C.S. (Eng.), Consulting Surgeon, British Expeditionary Force, France, with Foreword by Lieut.-General T. H. GOODWIN, C.B., C.M.G., D.S.O., Director-General Medical Army Service. New York: Oxford University Press, American Branch.

THIS volume is the result of the study of 2,500 cases of typhoid and paratyphoid fevers occurring in the British Expeditionary Forces in France during the war and is a brief but comprehensive presentation of this important subject. Since prophylactic inoculation against these diseases was not compulsory in the British Army, the author had the additional opportunity of observing the comparative incidence and severity of the complications among those unprotected and those who had received vaccine, even though the dose had been insufficient. It is interesting to note that the total number of complications were but 13.2 per cent. of the whole. It is also instructive to see that out of fourteen patients who developed intestinal perforation but one recovered. This complication still remains by far the most serious manifestation of the disease. The author had not seen, apparently, the report by Downs and Conner of a case of spontaneous rupture of the spleen with splenectomy and recovery. The book is beautifully gotten up, with numerous attractive illustrations, and although based on a comparatively small series of cases, the information it contains is the result of very careful study and for that reason has a high value.

THE PATHOLOGY OF PNEUMONIA IN THE UNITED STATES ARMY CAMPS DURING THE WINTER OF 1917-18. By WILLIAM G. MACCALLUM, M.D., Contract Surgeon, U. S. Army. Monographs of the Rockefeller Institute for Medical Research. No. 10. April 16, 1919. Price, $1.50. New York: The Rockefeller Institute for Medical Research.

IN this monograph MacCallum has presented an exhaustive and careful study of the autopsy findings in a fairly large number of the fatal cases of pneumonia which appeared in the army camps in the winter of 1917-18. These were frequently, though not always, associated with measles, and differed somewhat, at least bacteriologically, from the cases which developed during this last winter. He has classified the cases into the three general types of interstitial bronchopneumonia, lobular pneumonia, and lobar pneumonia, with groups of borderline cases. The discussion is detailed and rational, and supported by numerous case reports. Nearly one-half of the bulk of this volume is made up of a series of photographs which well illustrate the points the author has made.

RECHERCHES RÉCENTES SUR LES ICTÈRES. Par Dr. M. BRULÉ, Chef de Laboratoire à la Faculté de Médecine de Paris. Prix, 4 fr. 5. Paris: Masson et Cie., 1919.

THE present volume we take to have been interrupted by war activities and to have come into its own when the war was over. It is very unlikely that such an exhaustive study could have been prosecuted during the four years of interim. Of the scores of references cited the very large majority bear antebellum dates. We can do little more than announce the subject matter as listed in the table of contents: Theories of icterus; descending infection of the bile passages; pathological anatomy; tests for biliary retention; dissociated retention; latent retention; urobilinuria; hepatic insufficiency; hematogenic icterus; secondary biliary retention; various complementary phases, including the differentiation between hemolytic and hepatic icterus.

PYE'S SURGICAL HANDICRAFT: A Manual of Surgical Manipulations, Minor Surgery, and other matters connected with the work of House Surgeons and Surgical Dressers. Edited and largely rewritten by W. H. CLAYTON-GREENE, B.A., M.B., B.C. (Camb.), F.R.C.S. (Eng.), Surgeon to St. Mary's Hospital, Lecturer on Surgery in the Medical School, etc. Eighth edition; fully revised, with some additional matter and illustrations. Price, $6.00. New York: William Wood and Company, 1919.

IN this volume will be found much which the larger works on surgery are careful to omit, such as many of the common details and complications of treatment which occur in the course of surgical practice. The arrest of hemorrhage; the management of shock; the application of bandages and splints; fractures, dislocations, and sprains; the dressing of wounds, burns, and ulcers; the treatment of syphilis and gonorrhea; minor surgery, in general; and the treatment of various emergencies—these and many other similar topcis are here handled in a masterly way. The contents of this book will be found of more immediate practical service to the average medical student than most of the more pretentious textbooks.

CLINICAL CASE-TAKING, an Introduction to Elementary Clinical Medicine. By ROBERT D. KEITH, M.A., M.D. (Aberd.), Lecturer in Clinical Medicine, King Edward VII Medical School, Singapore; Consulting Physician, Tan Tock Seng's Hospital, Singapore. Price, $1.50 New York: Paul B. Hoeber, 1919.

IT is exceedingly important that the young medical student be taught to obtain his information and to arrange it systematically. It is only by such proper classification that he will be able to correlate different facts, and from them to make such logical deductions as to result in correct diagnosis and efficient treatment. This small book was written with the idea of presenting to the students in medicine an extensive scheme whereby they should learn to take histories and make physical examinations in a regular and systematic manner with minimum loss of time and without forgetting things. It is not, and the author never intended it to be, a complete manual of physical diagnosis, but it outlines a sequence according to which the examination may be made and which, if followed, would result in very thorough work. At the end of the work is appended a few pages which include a brief description of the more important examinations of the feces, sputum, urine, and blood. The book is well planned and written, and can be recommended to those who wish such a work.

RECONSTRUCTION THERAPY By WILLIAM RUSH DUNTON, JR., M.D., Assistant Physician at Sheppard and Enoch Pratt Hospital, Towson, Maryland; Instructor in Psychiatry at the Johns Hopkins University; President of the National Society and of the Maryland Society for the Promotion of Occupational Therapy; Secretary of the Maryland Psychiatric Society. Illustrated. Philadelphia and London: W. B. Saunders Company, 1919.

RECONSTRUCTION therapy is a new and popular phase of medical science. It has come into greater prominence since the war, and there is danger lest the enthusiasm of some of its advocates may do harm rather than good. Reconstruction therapy, like all other branches of the healing art, requires certain definite knowledge on the part of its practitioners; and it is the aim of this book to supply this knowledge and also to show what has been accomplished by the judicious application of this new phase of therapeutics. Properly applied, reconstruction therapy is of service in surgical, medical and mental cases; always provided, of course, that the cases are properly selected and that the "therapy" is administered in a proper manner, by one who knows what he is about. The book before us should prove of distinct value to the physician and the nurse; its well-selected bibliography is not the least of its many good features.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Fortieth Annual Meeting, Held in Atlantic City, N. J., June 16, 17, and 18, 1919.

THE PRESIDENT, DR. LEWIS S. PILCHER OF BROOKLYN, IN THE CHAIR.

First Day—Monday, June 16.

The Influence of War Surgery Upon Civil Practice.—Dr. LEWIS STEPHEN PILCHER of Brooklyn in his presidential address referred to the distinct surprise which had come to the assembly of the International Surgical Congress in New York in 1914, when President Depage announced as the theme of his inaugural address "War Surgery," for was not such an assembly to which his words were addressed a guarantee of the continuance of that peace of the triumphs of which those men were such eminent representatives? Yet before that address had appeared in print the world had been plunged into a strife which was to separate those representatives as enemies, to array in battle sixty millions of men, and to cause the direct loss from the world's workers of more than ten millions of men. Of the active members of the American Surgical Association a large proportion had worn the uniform of their country's service. Of the remainder there was not one who had not regretted that by reason of years or of civil duties it had been impossible for him to follow his younger colleagues. Those who had sealed their devotion to duty, their patriotic fervor, and their professional enthusiasm with their blood belonged to a legion of honor more illustrious than that of any modern government. The cross that marked their graves indicated a distinguished service of which no other badge could be more significant. That in this most recent of wars there had been inaugurated the most important and desirable change of granting to medical men degrees of rank suitable to their responsible duties Dr. Pilcher felt was an act meriting an expression of appreciation by the medical profession. The granting of degrees of rank to medical men had to do with that intangible, indefinable, altogether admirable thing called "morale," which Dr. Pilcher regarded as the surest precursor of success and the most important element in the attainment of ultimate victory. The American Congress in establishing in the medical corps the higher grades of rank gave to that branch of the service deserved recognition, and with it increased in a notable manner the morale of the whole service. Dr. Pilcher expressed the belief that the highest, most important, most beneficent of contributions of the surgery of the late war to the civil life of the nation was a quickened, ennobled, more efficient body of surgeons, who in the hard school of war had received an endowment of enthusiasm, an illumination of spirit, and an ability to persevere and to succeed under difficulties, which qualities they would retain through life and in some measure transmit to or create in their successors.

General Considerations as to the Treatment of War Wounds.—Dr. ANTOINE DEPAGE of Brussels, Belgium, regarded the scientific contributions to surgery in the late war as epoch-making. In consequence of the fact that the majority of wounds were, at least, contaminated, débridement had become a formal indication of first rank. Since January, 1915, they had followed at l'Ambulance de l'Océan débridement and "epluchage," with primary suture, in favorable cases, or secondary suture as soon after dressing as the surfaces of the wound indicated clinical asepsis. Emphasis was placed upon the method of application of the Carrel-Dakin solution. The following was given by Dr. Depage as his regular mode of procedure: (1) Upon admission of the patient the injured region was shaved, and then washed with a neutral solution of oleate of soda. (2) Débridement and epluchage of the wound were practised immediately thereafter. (3) At the same time the Carrel tubes were introduced to the bottom of the wound in such fashion as to permit the irrigation of the entire wound surface. (4) Application to the entire surroundings of the wound of compresses smeared with vaseline in order to prevent irritation of the skin. (5) Dressing with compresses of absorbent material. (6) After the return of the patient to bed, the Carrel tubes were connected up with the receptacle containing the Dakin solution and irrigation was carried on every two hours, controlled by a simple pressure forceps. (7) The dressings were renewed every day, careful lavage of the wound being made with oleate of soda. Until a regular determination of the abundance of the microorganisms in the wound exudates had been made it had not been possible in Dr. Depage's work to obtain all the benefits of the Carrel method. Such bacteriological control was then repeated in the same wound every two days, tracings being made of the microbic strength. Infected wounds were rendered sterile by Carrel treatment in from six to eight days. To better determine the most favorable moment for suture, the bacteriological control had been supplemented by cultures instituted regularly after débridement and before the suture. The conclusions from this study were: (*a*) For wounds feebly infected from the first day with ordinary microbes suture was permissible when at the second examination the smear yielded only one microbe in a visual field. (*b*) For wounds strongly infected by ordinary microbes, resort to suture might be made from the moment when the curve came down to one microbe in four fields. (*c*) In cases of streptococcic infection suture should not be instituted, but the wound should be treated, preferably by the Carrel method, suture being delayed until the streptococci had disappeared or become sufficiently attenuated to permit primary union. Streptococcic vaccination might here render the greatest service. The paper further dealt with the indications for immediate primary, delayed primary, and secondary suture, the consideration of peculiarities arising from the organ or tissue wounded, and with the results of suture. From June, 1916, to November, 1917, in thirty-one secondary sutures after amputation there had been twenty-six complete successes, four partial successes, and one failure. In joint wounds there was shown the superiority of immediate suture after wide arthrotomy and closure of the joint cavity, over any other method of treatment. In wounds of the elbow and shoulder, however, in Dr. Depage's opinion, the Carrel treatment followed by secondary suture or by cicatrization by second intention was indicated.

The Most Important Factor in the Treatment of War Wounds and the Most Important Factor in Civil Surgery—the Good Surgeon.—Dr. GEORGE W. CRILE of Cleveland said that after four years of intensive study there was emerging from the conflict of views regarding the treatment of wounds a universal recognition of the good surgeon as the one agent of successful military surgery. Thus the vast experience in traumatic surgery had taught the profession the lesson already learned in civil surgery, that sound surgery only would bring success. The wound surgeon, the author asserted, considered the wound as well as the patient, respected the tissues of the anesthetized man as well as of the unanesthetized, played all the defenses and reparative forces of the patient, was the exponent of no single method, but adapted his methods to the military situation, the possibilities of after-care, and the type of transport—seeing clearly the tomorrow of the wound and weighing accurately his chance for success.

The Problem of the "Slightly Wounded" in Military and Civil Practice.—Dr. WILLIAM E. LOWER of Cleveland observed that the great war had supplied to medical officers a postgraduate course in organization, transportation, sanitation, hospital construction, management of supplies, treatment of every kind of wound by every variety of method, and in noting what not to do. The tendency in rush periods to leave the slightly wounded to the attention of the less trained men had proved a dangerous hazard to the man power of the army. The equal importance in civil practice was especially marked in the smaller manufacturing plants. In many hospitals also there was the tendency to turn over to inexperienced operators the care of minor injuries. With the serious resultant effects which had been too long endured all were familiar, and the author felt that the American Surgical Association should emphasize the need of proper organization to assure better attention to the less as well as to the greater injuries, to the minor as well as to the greater operations.

What Would Be the Benefit to the Civilian Surgeon of the Experience Gained by Our Military Surgeons in

the Recent World War?—Dr. Edgar A. Vander Veer of Albany in this paper said that early in the war the attempt at aseptic technique had broken down and that the system of treatment of fractures by the Allied surgeons had revealed great confusion. In the treatment of wounds army surgeons had been obliged to return to antiseptic methods and such experiments had led some British surgeons to abandon almost entirely the use of strong germicidal solutions, finding that sterile water alone maintained satisfactory healing conditions. While the Carrel-Dakin method had accomplished much, Dr. Vander Veer felt that it was an expensive, painful, and somewhat protracted line of treatment. The antiseptic treatment, however, had been employed to a great extent in the third and fourth years of the war. Reference was made to the excellent system of transportation which had been developed and to the short history accompanying the patient, both of which had spared the patient much suffering. The standardization of splints in the treatment of fracture had been of great benefit and their proper application, with the use of tetanus antitoxin, had, in the author's opinion, lowered the mortality. Ether and chloroform he believed would continue to be the most reliable anesthetics.

The No-Flap or Guillotine Amputation; An Unfortunate Resurrection.—Dr. John H. Gibbon of Philadelphia gave as the reason for deprecating this form of amputation the frequent secondary hemorrhages, slow healing, the painful dressings, and the numerous secondary operations following the no-flap amputation. These complications were, in his opinion, obviated by the reflected skin-flap amputation. The additional time required for making the reflections of the flap, he said, occupied but a few minutes and could not add to the shock. As soon as the wound had become clean the flaps were in readiness to cover it; whereas, in the no-flap method a second operation or the employment for a number of weeks of some appliance to draw down the skin was necessary, and in many instances such efforts failed. While one reason given for doing the no-flap operation was that it gave a good stump for the wearing of an artificial limb, in Dr. Gibbon's opinion the reflected skin-flap amputation gave exactly the same kind of stump, gave it earlier, and with less pain and danger. Were this not true, then the guillotine amputation was to be employed in civil practice, which procedure he doubted anyone would be willing to inaugurate. Dr. Gibbon referred to the obligation he felt every surgeon working in France owed to Dr. Depage. To him more than any other man were they indebted for their treatment of war wounds. Differing in his experience from that of Dr. Crile, he had seen practically no benefit from blood transfusion in acute infection. Men badly shocked would be braced up for a time and then die. This experience had obtained in the advanced hospitals. With reference to the patient's reaction to infection, he also was not in accord with Dr. Crile. While he had seen many men wounded in Belgium under the worst conditions of winter, and again in a much pleasanter part of the world in the spring and summer, he had observed no decided difference in the reaction of the indiviual patient to infection. Acknowleging that in the treatment of wounds the first operation should be thorough and complete, he did not believe that the use of antiseptics could be eliminated in the sterilization of infected wounds.

Dr. Thomas W. Huntington of San Francisco paid a tribute to the trained nurse in war surgery. In Italy, where it had been at first thought inadvisable to have her, those in charge of the hospital work had later said they would be helpless without her. He believed that the encomiums of the trained nurse should be recorded in history.

Dr. Alexis V. Moschowitz of New York observed that while it was well known that the Carrel-Dakin treatment would never take the place of good surgery it was a wonderfully valuable aid in the treatment of infected wounds. Given the choice of the two agents he would by all means take good surgery; if, however, he could have good surgery and the Carrel-Dakin treatment as well he would be well equipped.

Dr. Henry H. M. Lyle of New York emphasized the danger of the general use of nitrous oxide except in the hands of men experienced in its employment.

Dr. George E. Brewer of New York regarded as the most important step in the treatment of shock during the war the organization of the shock team. This consisted of two men expert in the treatment, and from two to four each of nurses and orderlies. In the shock wards were every appliance for blood transfusion and other means of stimulation. The teams which had been installed in every front area hospital had, so far as he knew, been continued to the end of the war.

Dr. Howard Lilienthal of New York reported his experience in blood transfusion as differing from that of Dr. Gibbon. In the case of a patient who had lost blood, whether or not he was septic, the most powerful influence for good was the replacement of blood. This was a matter of pure mathematics. In his opinion there was nothing quite so good in profound anemia with sepsis as blood transfusion.

Dr. A. P. C. Ashhurst of Philadelphia recalled that in 1915 Dr. Depage had pointed out that, if in the first six hours the red blood count fell below 4,000,000, practically all the wounded died unless transfused. He felt it important that this should be remembered, and emphasized the importance of knowing the full truth concerning war surgery.

Treatment of Recent Wounds of the Knee Joint.—Drs. Eugene H. Pool of New York and John H. Jopson of Philadelphia contributed this paper, giving their observations based upon 34 cases in which they had operated. The principles of treatment were summarized as follows: Complete débridement of the tract of the projectile through the soft parts and bone, removal of foreign bodies, thorough irrigation of the joint, distention of the joint with ether, absolute closure of the joint by suture, primary or delayed closure of the superficial parts according to the rules laid down for primary suture of the soft parts alone; finally, early active motion. In extensive involvement of the articular surfaces effort should be made to save the joint, provided the conservable articular surfaces and soft parts were sufficient to warrant the hope of a useful joint. It was to be remembered that stability of the knee was essential. When the joint could not be saved the question of extensive resection and amputation was to be carefully considered. With suspicion of infection aspiration was at once indicated with the making of a culture. In suppurative arthritis the important feature was early drainage. This was best instituted by lateral incisions well back, though occasionally an incision elsewhere might be employed. Drains should not be used. Splints were to be dispensed with or arranged for support without joint fixation. Free mobility every two hours so that the active movements would evacuate the joint should be enforced.

Report of 82 Knee Joint War Injuries with a Discussion of the Willems' Treatment.—Drs. Clarence A. McWilliams of New York and William B. Hetzel of Pittsburgh in this paper made a plea that the old immobilization treatment be discarded for the Willems' immediate, continuous, active mobilization procedure. In 32 of the 82 patients no fracture was present; in 8 there was simple fracture; in the remaining 40 there were combinations of comminuted fractures; 57 cases, or 68 per cent., remained clean. In only 6 cases were the joints drained. In 36 of the clean cases 9 had perfect function finally; 8 were ankylosed; in 24 there were varying degrees of motion. Seventy-three cases became infected, of which 4 finally became ankylosed; 1 was resected; 3 had amputations; 4 died of the infection; 1 had flexion of 90°, while the results in 3 were unknown. Compared with these melancholy results of immobilization the statistics of Willems in 100 knee cases, 18 of which became infected, showed no deaths and no amputations, 1 resection, and 2 stiff joints. Of the authors' cases 9 had died. The authors believe that no joint should be evacuated within ten days after operation, that the joints should be completely closed at operation, that no splint should be used after operation, except where fragments would otherwise be displaced. They advocated that the Willems after-treatment of immediate, continuous, active mobilization be continued day and night in both aseptic and septic joints. In their opinion there should be in every hospital a day and a night nurse to see that these active motions were carried out.

Transthoracic Laparotomy.—Dr. Willy Meyer of New York said that in cases of injury, by way of the

chest, to organs in the vault of the diaphragm it had been found best to attend first to the damage wrought in the chest and then to try to deal with the injured abdominal organs by a transthoracic laparotomy, *i.e.* by either incising the diaphragm or enlarging the wound in the same. Sauerbruch, the first to proceed systematically along such lines, had reported three cases successfully operated upon, in all of which a differential air pressure apparatus had been employed. Stress had been laid by Sauerbruch upon the importance of incising the diaphragm transversely or obliquely to the direction of its fibers in order to avoid injury of the phrenic nerve. In a case of accidental shot wound injury, operated upon by Dr. Meyer in January of the present year, the bullet had entered the thorax in the sixth interspace, fracturing the seventh rib and becoming lodged in the convexity of the liver. Pus had been unexpectedly found in the liver, indicating a beginning hepatic abscess and showing the wisdom of deciding to operate. This, in Dr. Meyer's opinion, also proved the importance of operating under differential air pressure in such cases, since the pleural cavity was found to be free of adhesions. In this way the otherwise inevitable occurrence of an acute pneumothorax was avoided. Drainage was considered the only safe course in view of the unknown character of the pus found. An uninterrupted recovery followed. Dr. Meyer expressed his belief that bullets in thoracic as well as abdominal organs were probably best removed, that the question of whether operation should be done immediately after the accident or later, depended upon the seriousness of concomitant symptoms, that simultaneous injuries to chest and abdomen, as also injuries to the convexity of the liver or the spleen, without previous penetration of the chest, if not accessible from below, afforded an indication for transthoracic laparotomy. Involvement of intraabdominal organs could be determined before or during thoracotomy. These operations, he believed, were best done with the help of some differential pressure apparatus. Air-tight and water-tight drainage of the chest (Kenyon's) he regarded as the safest procedure for the after treatment.

Dr. William H. Stewart of New York emphasized the importance of the use of differential air pressure in connection with the work described by Dr. Meyer and showed lantern slides of *x*-rays of the abdomen taken after inflation with oxygen or air. A point for the injection of the oxygen, he explained, was selected below the umbilicus on either side, keeping away from adhesions. He used an ordinary lumbar puncture needle with a rubber bag filled with oxygen from which about one litre was gently passed into the peritoneal cavity, the amount being dependent upon the degree of relaxation of the abdominal muscles. Two factors causing apprehension were infection and the possibility of puncturing the gut. The former was to be overcome by the ordinary precautions. Concerning the second, it was known that the intestinal muscle showed a tendency to recede from a sharp article. This had been shown in the *x*-ray by the passage through the gut of the open safety-pin. It also had been demonstrated that with a needle passed into the abdominal cavity of a live rabbit the intestine would recede; when the rabbit died puncture would occur.

The Treatment of Gunshot Wounds of the Chest.—Dr. Ellsworth Eliot, Jr., of New York stated that the treatment of gunshot wounds of the chest was either conservative or radical, that the former was almost always the rule in civil practice, and that the latter was occasionally justifiable for overcoming infection, especially in the chest wall. He emphasized the fact that this dreaded complication became less frequent as the lung was approached and was uncommon in wounds of the viscus, even in the presence of hematoma or hemothorax. Whether this was due to the removal of foreign and infectious material from the surface of the projectile in its passage through the chest wall, or to the greater resistance of the lung to certain forms of pyogenic infection was not yet known. Only cases associated with hemothorax, because of the increased susceptibility to infection, were reported in the paper. In all, early aspiration was done. Several times the measure had been repeated, and in two cases of failure a thoracotomy was done under local anesthesia, with extremely satisfactory result. One fatality had occurred in a case in which infection of the entire pleural cavity had developed prior to admission, and a second fatal result had been due to a serious associated complication. While the number of cases was not large, the result was regarded as much better than that obtained by the immediate removal of the projectile. The result of secondary operation, should infection develop, was believed to be much more favorable because of the improved general condition of the patient and the fact that formation of adhesions limited infection to a segment of the pleural cavity, thereby greatly diminishing the operative risk.

Dr. Howard Lilienthal of New York said that a developing pneumonia of the opposite lung had been the cause of bad statistics in the treatment of gunshot wounds of the chest. Such a pneumonia would appear whether or not operation were done. He had seen fatal pneumonia in these cases in which no other cause of death could be found. In performing aspiration he used instead of a needle a fine trocar and cannula to which a rubber bag was attached so that the fluid would siphon out. To prevent the formation of a pneumothorax he explained that it was only necessary to have the patient by an expiration force the lung into contact with the pleura, while the operator had the end of the tube still under. At the cessation of the expiration the cannula should be removed. An *x*-ray would show the lung in absolute contact with the chest wall.

Dr. Eliot in closing said that their results by the conservative method had been so uniformly good that the radical procedure was not regarded as necessary or advisable.

(To be continued.)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 24, 1919.

The President, Dr. Charles H. Peck, in the Chair.

Report of Legislative Committee.—Dr. George W. Kosmak reported that the committee had attended the hearing on the Davenport-Donohue bill, providing for compulsory health insurance, which was held in Albany on March 19. Of all the arguments made by the opponents of the bill those of the medical profession were the most effective and convincing. The medical profession had made a very good representation before the committee. It was very uncertain what course the bill would take, though undoubtedly it would undergo more extensive amendment before any action was taken upon it.

After the adoption of this report, the Society plunged anew into the discussion of compulsory health insurance. During the course of the discussion resolutions were introduced cautioning representatives of the Society in the conferences with the proponents of the health insurance bill not to discuss the subject from any standpoint of compromise that would convey the impression that if the bill were amended it would meet the approval of the medical profession. It should be definitely understood that no matter how amended or in what form it appeared they were still opposed to the principle of public health insurance. This measure was defeated. The only action taken was that of appointing a committee to appear at a hearing to be given before Governor Smith in this city.

Personal Experiences with Thoracic Surgery with the American Expeditionary Forces.—Col. Howard Lilienthal, in an informal talk, said that there were three classes of thoracic conditions with which he had been brought in contact. These were (1) diseases of the pleura and lungs, such as empyema, lung abscesses, etc.; (2) conditions resulting from old gunshot wounds, such as were seen at the base hospitals, and (3) recent gunshot wounds, such as were met with in the front line hospitals. The speaker's first extensive experience with thoracic conditions in France was at St. Nazaire, where the percentage of pneumonia cases developing empyema was very high. The pneumonia cases were brought from the ships to the base hospital at this port, and of one series of 60 ship pneumonias 33⅓ per cent.

developed empyema, while only 9 per cent. out of 417 pneumonias from other sources developed empyema. These figures must be taken without comment or explanation, since all the conditions were not known. In this hospital 70 per cent. of the empyema sinuses had not healed during periods ranging from six weeks to six months, and every one of these cases showed blue pus, a constant elevation in temperature, and all had had rib resections. Another difficulty with which they had to contend with at St. Nazaire was flies. These were so numerous that it was impossible to keep them from getting into the wounds during dressing, in spite of the efforts of an attendant to drive them away. There were thirty-one of these patients and he began by examining them all by the *x*-ray, most of them receiving a fluoroscopic examination. Of the thirty-one he found that ten required surgical operation, while the rest were cured by proper disinfection of various kinds. In the past many chronic empyemas had been treated by rib resecting chest collapse operations of various kinds, but this procedure at the same time put the lung permanently out of commission. In this series of 31 cases 90 per cent. were cured by Carrel-Dakin disinfection of the sinus. Dr. Lilienthal described a method of performing intercostal thoracotomy without rib resection which he used in the cases in this hospital which required operation. The operation was performed under positive pressure intrapharyngeal anesthesia. They had had one case of bronchial fistula, without cavity, which was cured by the injection of bismuth paste employed for diagnostic purposes, and after that he had used this method with satisfactory results in a number of other similar cases. The results obtained by this method of intercostal thoracotomy without rib resection were so satisfactory that in submitting the report from this hospital a recommendation was made that the procedure be employed in the hospitals near the front lines in the exploration of the thorax and the extraction of projectiles. Following this Colonel Lilienthal said he was assigned to Evacuation Hospital No. 8, where he had charge of much of the thoracic work together with Major Brickner and Captain Kellogg. They had 67 cases of recent gunshot wounds of the thorax, and of these 16 were not operated upon. Of the 51 operated upon 27.4 per cent. died. Of the 16 patients not operated on only one died, but this did not mean that operation was responsible for the large proportion of deaths, since these patients required no operative interference. In these cases the damage was done by different kinds of projectiles and the men came into the hospital at times varying from a few hours to four days after the receipt of the injury. Completely perforating wounds, with entrance and exit and no foreign body remaining, occurred in 21 instances, with two deaths, or a mortality of 10 per cent. No large operations had to be performed in these cases, often the simplest debridement sufficing, as the hot machine gun bullet striking the chest squarely made what was probably an aseptic wound. Bullets, however, striking the chest at a slant and fracturing several ribs made very destructive wounds, as in one instance in which a machine gun bullet struck near the angle of the eleventh rib. The missile, traveling upward, fractured the next five ribs in the same location, and then passed through the external soft parts and out through the axilla. There was an enormous wound of the abdomen, diaphragm, and thorax, so that portions of the stomach, spleen, omentum, and colon prolapsed into the wound. This patient, however, was doing well when the surgical team left the hospital. On the other hand, wounds made by high explosives were very likely to be infected, especially by the gas bacillus, and the pleura was very susceptible to gas bacillus infection, and to anaerobic infection from the larger bronchi. The large rough wounds made by fragments of shell were most dangerous and had to be operated on immediately. Those made by machine gun bullets could sometimes be relieved by aspiration and relief of the hemothorax. In cases in which there was no hemothorax the patients were sent back to the base hospital. The care of thoracic wounds at the base hospitals was not a simple matter for frequently apparently slight wounds were found to be infected with the streptococcus hemolyticus or gas bacillus and were followed by empyemas which required surgical interference. In speaking of the localization of missiles, Colonel Lilienthal described the work done by the roentgenographic department, which was under the direction of Captain Alleman. The speed and accuracy with which foreign bodies were located was worthy of the highest commendation. Captain Alleman and his staff examined as many as 30 patients an hour and seldom made a mistake.

Dr. NATHAN W. GREEN said that as he recalled it Dr. Lilienthal made the statement that at the Base Hospital at St. Nazaire he had found about 70 per cent. of the chronic empyemas with unhealed sinuses. Without any intent at criticism of the men in charge of this hospital he would like to ask if Dr. Lilienthal knew whether they had tried to put these patients on bottle blowing. He had found that if patients with open sinuses were put on the bottle blowing exercises as soon as they were able to make the effort the sinuses did not persist so long. Of course this was not a new observation. The operation which Dr. Lilienthal did for chronic empyemas was a very good one to follow, but he felt that a note of caution should be sounded. Dr. Lilienthal had described the operation as appearing quite large but really quite simple. It was really quite a large operation on an individual whose vital powers were depleted. He had lost two patients from seven to nine days after a multiple rib resection, due to the fact that the e patients did not stand so long an operation well. One hour was as long as he subjected such a patient to operation at the present time, and he would rather cut the time down to 40 minutes. The war had done much to bring to public notice many things that had been quietly going on in scientific circles. Among these might be mentioned the surgical treatment of conditions arising in the chest. It was very rarely nowadays that a new principle sprang fully grown into being. In times of stress search was made for what had been worked out in individual clinics and in laboratories and after scrutiny whatever seemed good was applied clinically. This was true of surgery of the chest. As far back as 1876 Woillez invented some sort of a negative pressure chamber for aiding artificial respiration. More recently the names of many surgeons with which we were familiar were associated with advances in thoracic surgery. The war had furnished a vast amount of clinical material—both of a traumatic nature and due to pathological conditions in this specialty. A better understanding of the treatment of empyema had resulted from the recent epidemic of influenza. In the traumatic field, injuries of the chest might be divided into the severe injuries resulting from a widely opened pleura, with extensive injury to the lung; and into perforating wounds of the chest with only a limited tract of injured lung. It was in the widely opened chest that the advance in the treatment of war wounds of the chest had been most marked. Here the removal of the crushed and lacerated tissue and the primary suture of the lung had been applied. In the penetrating wounds of the chest, conservatism and expectant treatment was still to be recommended. In all these injuries the question of thoracic drainage was most important. Some observers preferred to close the chest completely in early cases and await the accumulation of fluid. Others preferred to establish drainage in order to anticipate the occurrence of an infectious pleurisy. In the wounds of the great vessels of the lung, the hemorrhage was so severe that frequently surgical intervention might not be applied. In the wounds of the smaller or peripheral vessels of the lung, the collapse of the lung might prevent immediate disaster. The physiological difference between conditions in the chest and in the abdomen had made the drainage of the chest after injuries somewhat of a problem. The negative pressure on the pleural cavity had made drainage a subject of serious study.

In traumatisms of the chest it was desirable to keep the pleura uninfected if possible—only opening it when infection had manifested itself by rise of temperature or the detection of septic fluid by the needle. In speaking of the advisability of closure of the chest in early cases, Dr. Green quoted statistics from an article by Col. H. M. W. Gray in the *British Medical*

Journal for November 3, 1917, from which it appeared that the operation with complete closure was 20 per cent. better than the operation with primary drainage. Col. Gray said: "It may be necessary to reopen the chest on account of the development of intrapleural sepsis or to remove a foreign body, but by the time this is necessary the patient has been tided over the dangerous period, and when the pleural cavity is drained there is not any more respiratory distress than after an ordinary empyema operation." Capt. J. C. H. Roberts and Capt. J. P. Craig, of the Royal Army Medical Corps, in speaking of the surgical treatment of the severe wounds of the chest remarked: "No cases were drained unless (1) the chest wall could not be closed owing to the condition of the patient, or (2) if infection of the lung or pleura, as distinguished from its contents, was definitely established." They further stated that: "We soon overcame our scruples about completely closing up cases with a streptococcal infection, but we must admit to a more gradual conversion to the idea of closing cases with anerobic infection. This, however, we have proved to be quite a safe procedure when the precautions we have enumerated have been carried out" (namely, clean surfaces left internally). Their operative work was done preferably under local anesthesia. Of the open sucking wounds with free air entry, of which they had 29, five out of 12 operated on recovered with the pleura closed and the wound closed. Seven died, making a mortality of 58.3 per cent. Of 17 in which the pleura was drained from the start, five recovered and 12 died, a mortality of 70 per cent. Dr. Frank Hathaway, in the *British Medical Journal* for November 3, 1917, advocated closing the pleura. All these observers agreed that the closed pleura cases in operations on war wounds of the chest did better than those with primary drainage. Dr. W. M. Boothby, writing in the *Boston Medical and Surgical Journal*, advocated the avoidance of negative pressure brought about by an aspirating bottle in cases of hemorrhage. He said, "After three days the danger of infection exceeds that of hemorrhage." Dr. Green stated that his personal experience in civil practice was that the danger of infection and hemorrhage went hand in hand. An elevation of temperature indicated the necessity of an exploratory aspiration. When the pleura became infected Dr. Boothby advocated free drainage by a long thoracic opening. In the question of drainage after traumatism of the lung, it seemed but common sense to have available some means of drainage which might be installed while the patient was under anesthesia and might be left closed, if there were no symptoms of the presence of infectious pleurisy, but which might be brought into play, without further disturbing the patient, if fluid should accumulate. Kenyon's method seemed to fulfill this requirement.

Dr. Willy Meyer expressed the opinion that there could be no doubt but that thoracic surgery would be the one department of surgery which would be pushed forward most by the war. It had been a matter of sheer necessity for many surgeons who had gone to France to do operations on the thoracic viscera they likely had never done before. They were to be commended for the spirit with which they went into the work, and for their achievements. However, while fully appreciating their successes, it must not be forgotten that their statistics did not cover the entire field of thoracic surgery. It should be remembered that more than 50 per cent. of men with chest injuries died on the battle field, and those who came to the field and evacuation hospitals were the ones who survived the acute stage of the injury, viz, the acute pneumothorax. Again we should not forget that these were all young men and not persons who had suffered from disease previously. By taking these facts into consideration one viewed the results at a little different angle than they have been stated. Dr. Meyer advised a little caution before assuming that thoracic surgery was just like abdominal surgery. He felt that it was a mistake to attempt to do thoracic surgery without having differential pressure apparatus at hand. In opening the chest and removing a bullet one was not working in and beyond a "virgin" pleura. The future of thoracic surgery rested on the acceptance of the principle known as the maintenance of differential pressure.

Reconstruction Operations in Cases of Cancer of the Face.—Dr. George H. Semken made this presentation. He stated that the series of slides shown represented an attempt to systematize, in part, the surgical treatment of cancer of the face, so as to meet the two indications—one, the radical extirpation of the growth, and the other, the repair of the resultant defect. In this presentation emphasis was laid upon the reconstruction work rather than upon the question of the cancer. The small growths were best destroyed with the galvanocautery. Larger growths were excised in the usual circular or elliptical manner, including a presumably safe margin of healthy skin and a larger segment of the underlying fascia. When the growth was favorably situated and not of large size, additional small excisions of the wound margins might be made, and after wide undercutting of these margins, the wound might be wholly closed by suture. Larger defects were covered with Thiersch grafts. Thiersch grafts were best used on surfaces having a firm base, such as the forehead, temples, and the nose. Cut bone surfaces and periosteum might also be covered with success in this manner. In some cases, owing to undue contraction of the underlying fibrous tissue, the Thiersch graft would be unsightly. In such instances, the graft-covered cicatrix might be split, as one would cut a thick slice of bread into two, and the outer portion removed, leaving a thin, smooth scar base which still held the tissues together. Over this a new Thiersch graft was placed, usually with good result. The obvious limitations of the Thiersch graft made it necessary to use flaps of skin and subcutaneous fat in many cases. These might be taken from the immediate neighborhood and left in vascular, lymphatic and nerve connection with the original site; or they might be taken from other areas, and, after a proper interval, completely severed from the parent site [Migration flaps]. Such flaps might be taken from adjacent regions, such as the forehead or the neck, or they might be taken from the arm, forearm or hand—the upper arm being usually chosen as most suitable. Definite rules could not well be laid down, as each patient presented his own problem; but illustrative cases, shown in the slides, indicated some of the procedures followed. Flaps from the forehead or the cheeks were used in blepharoplasty and in the covering of the orbit after exenteration of its contents. The site from which the flap was taken was then covered with a Thiersch graft. When feasible, in the cheek, the Thiersch grafted area was later excised, the wound margins were undercut, and the wound was closed by suture. For rhinoplasty flaps from the forehead or the upper arm were selected; and a secondary implantation of cartilage taken from the ear was done, to prevent collapse of the newly formed alae. Defects in the cheek required flaps from the neck or upper arm. Either the mucous membrane alone or the whole cheek might be replaced in this manner. For the replacement of defects in the upper lip suitable cheek flaps were used, with additional small mucosa flaps when necessary. The cheek flap was so planned that the posterior line of incision was far back on the face and therefore not visible to direct front vision. The Thiersch graft covering of the site of the flap was later excised and the area closed by suture. The procedure followed in the case of the lower lip was the classical V excision for smaller growths, and Dieffenbach's method of cheiloplasty for the total and sub-total resections. The extensive excision of the cervical lymphnodes was done in all cases of lip and mouth cancer and in some of the cheek cases.

Dr. Lilienthal said it was not right to allow a paper like Dr. Semken's to go without a word of commendation. He could say that he had never seen such a beautiful array of results in facial surgery as Dr. Semken had presented this evening. He had nothing but commendation for him. He wondered, however, if Dr. Semken was familiar with Theodore Dunham's method of taking a flap from the forehead, dissecting it free with the temporal artery as a pedicle, and using that to cover the defect. Even if he had used that or any other method the results he had shown could hardly have been improved upon.

Dr. Green said he was very much impressed by Dr. Semken's presentation. He had been dabbling in facial

surgery himself for the past 12 years, but he had never obtained such a series of artistic results as those just shown. Dr. Semken's results were due to a combination of the art of surgery and the science of surgery. A man had to be capable of a high degree of visualization in order to plan operations that produced such artistic results. He had been much interested in carcinoma of the upper lip. He had had one case in which he had removed a primary carcinoma from the upper lip and later there was a recurrence, several metastases appearing. The man was difficult to manage and delayed operation, until when he finally came to be operated on all the glands in the vicinity had to be dissected out and the man died three years after the primary operation from metastases at the base of the brain, but with no outward manifestation of recurrence to the eye. There was an impression that basal celled epithelioma of the upper lip did not metastasize, but it did. Probably the reason one did not meet with metastases oftener in epithelioma in this locality was because the cases did not go so long before placing themselves under treatment. He felt sure that all the members of the Society were grateful for the opportunity of listening to such a presentation as Dr. Semken had given them.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, February 26, 1919.

The President, Dr. B. F. Stahl, in the Chair.

Alkali Treatment Applied to the Acidosis of Epidemic Influenza.—Dr. Thomas C. Ely read this paper. Epidemic influenza, he said, was a concrete instance of acidosis, and given a condition of acidosis the medical treatment was elimination and the administration of the alkalies. In the recent influenzal epidemic he had employed this treatment with surprisingly good results. Reference was made to the fact that the textbooks affirm that infections from the streptococci and other pus germs and the pneumococci were always marked by pronounced acidosis, and that in the present epidemic all authorities agreed that these microorganisms were especially in evidence. Dr. Ely had had but one death which could be justly attributed to influenza. A physician in a rural district had written him that he had given the old alkaline fever mixture, liquor potassii citratis and spiritus aetheris nitrosi, freely to every patient, and had had only one death, and that was directly attributable to hemorrhage from a gastric ulcer. Dr. Andreus, a physician for a lumber camp in New Mexico, wrote that he had treated over 300 cases with only 5 deaths. He used the alkaline treatment, and all of his cases were treated under the most unfavorable circumstances, as he "had no nurses except laborers and lumbermen, and at one time had seventeen sick patients in five beds." This Dr. Ely observed was in striking contrast to the high mortality often seen in urban practice with neglect of the alkalies. In 26 cases of pneumonia, with well-marked crises, over 100 cases of lobular pneumonia, 5 pregnant women, and 11 instances of severe intestinal infections, he attributed the large number of recoveries to the persistent use of early elimination and saturation of the system with alkaline bases, avoiding any remedies which checked secretion, as opium or belladonna, or any heart depressant, such as aspirin, or any influenza vaccine or serum. Reference was made to the teaching of physiology that if the alkaline reserves of the body have been withdrawn the poison acids cannot be neutralized, and that life cannot be preserved unless the bases, sodium, potassium, and calcium are supplied. The explanation of the success of the elimination and alkaline treatment was therefore obvious. Alonzo Taylor was quoted as saying that "If the acids were but eliminated entirely as ammonium salts, all would be well, but as they circulate they abstract from the tissues sodium, potassium, and calcium, and disturb the equilibrium of the basic elements in the tissues. Obviously the correct therapeutic measure is not to administer an alkali of one type, as sodium bicarbonate, but a mixture of sodium, potassium, and calcium, in order that all these may be present in abundance in the tissues and the equilibrium of the fixed alkaline bases in the central nervous system be thus maintained." Since too much alkali might produce an alkalosis the limits of moderate alkaline dosage must be observed. The use of sodium and alkalies should be under the guarded care of physicians, and their promiscuous use by the public was to be condemned. The technique of Dr. Ely's treatment was given as follows: Immediate elimination by profuse sweating and divided doses of calomel, 1/10 grain every half hour until 1 grain or more is given. Water exclusively was given for the first 24 or 48 hours, and water was also given freely by mouth or by bowel throughout the attack. Sweating was produced preferably by drinking large bowls of hot boneset tea. Hot mustard foot baths were always used. At the outset and during the attack sodium bicarbonate, potassium citrate, and the calcium salts were administered, the latter in the form of lime water. To every patient he gave a teaspoonful of sodium bicarbonate to a pint of lukewarm water every four hours by enema. To spare the overworked druggist Dr. Ely had given routinely the simple prescription:

Sodium bicarbonate	½ ounce
Peppermint water	4 ounces

Teaspoonful every 2 hours.

Alternating with:

Potassium citrate	½ ounce
Peppermint water	4 ounces

Teaspoonful every 2 hours.

The calcium salts he gave in the form of lime water, one-third, and milk, two-thirds.

He had employed the common cardiac and respiratory stimulants. From the beginning of the attack the patient was given orange juice and lemonade freely. In considering the physiological action of the foregoing treatment attention was called to the fact that in man there was a continuous output of carbon dioxide through the skin and that the increased work of metabolism of the sweat glands increased the carbon dioxide. This was a significant factor for, as observed by Brubaker, it was probably carbon dioxide, due to the absence of alkaline bases, which chiefly gave patients the dark cyanotic hue, which had given rise to the popular name the "black plague." Serum treatment might be rational and scientific if the microorganism causing the disease had been isolated with certainty. All were familiar with numerous reinfections, and it might be questionable whether a passive immunity could be induced for a disease which itself did not produce an active immunity. The question was raised whether influenza serums and vaccines had proved to be harmless.

Appreciating the wonderful accomplishments by the bacteriologist in typhoid fever, diphtheria, tetanus, and many other diseases, the author asked whether there was not a growing tendency to give too much weight to bacteriology and serology to the exclusion of physiology, pathology, and physiological chemistry? Dr. Ely considered that the chief cause of death in this epidemic had been the overwhelming acidosis, and the object of his treatment had been to prevent the formation of such acidosis by the administration of the essential alkalies.

Acidosis in Children.—Dr. J. P. Crozer Griffith presented this communication. He said that acidosis, in contradistinction to acetonuria, indicated a decrease in the alkali of the blood irrespective of the actual amount of acetone bodies which was being excreted; that was accompanied by a decrease of the carbonic dioxide tension of the alveolar air, an increase in the hydrogen-ion concentration of the blood, and a great lessening of the reserve of the alkali in the blood. Two facts brought prominently to attention in the matter of acidosis in children were mentioned. The first depended upon the statement that acidosis and acetonuria were distinct. It was only by the occurrence of *symptoms* of acidosis or by laboratory tests that the relative excess of acid in the blood and tissues could be determined. Equally important was the second fact, that children seem especially prone to develop symptoms of acidosis. This might depend upon the small reserve of alkali characteristic of early life, or upon the facility with which children manufactured the acetone bodies without any discernible sufficient reason. Although acidosis in con-

nection with diabetes in children was naturally thought of there were other causes which seemed more frequently operative. The author had seen a diabetic girl, three and a half years old, plunged from a splendid general condition into a fatal coma by an ill-considered change in diet. In recurrent vomiting attributed to acidosis he had never been able to convince himself that acidosis was present. A prominent cause of acidosis, especially in infancy, was severe diarrhea of the non-inflammatory form in which there was a large loss of liquid from the intestine. In all cases in which the development of acidosis was feared free administration of alkali was advised, especially bicarbonate of sodium, and enough should be given to keep the urine alkaline. If given subcutaneously it must be especially prepared; boiling for sterilization rendered the solution very irritating. So far as preventive treatment was concerned, unfortunately there was little to guide one in the matter of anticipating the condition.

Acidosis in Pregnancy.—Dr. COLLIN FOULKROD read this paper. He expressed the hope that there might soon be a national, impartial, non-individual cabinet of experts who would in an unbiased manner seek theories of relief and give them a thorough laboratory and clinical try-out. If there was meant by acidosis a displacement of the free alkaline content of the blood by the volatile fatty acids a picture was being discussed which had not yet been thoroughly worked out in its relation to pregnancy. If, on the contrary, there was meant a superficial clinical picture of conditions which were relieved by alkaline treatments as a diagnostic point without laboratory investigation there might be found some application in pregnancy. The crucial point in acidosis was the reduction of the reserve alkaline contents of the blood below a point which would enable it to carry off the carbon dioxide in the tissues to protect the internal respiration. In both internal and external respiration of the complicated metabolism of pregnant women, certainly at some point, when disturbed, evidence of acidosis appeared. Recalling that ammonia played a protective part in the blood in preserving the normal free alkaline contents it could be seen that the digestion of proteins in the liver and the catabolism of fats into the fatty acids were interrelated; so much so that Zweifel not only diagnosed acidosis as the cause of eclampsia, but identified the specific acid as sarcolactic. It had occurred to Dr. Foulkrod that acidosis might be simply one stage in the toxemic conditions, it might even be a fatal stage, and yet the principal cause of these different toxemias might be different, as for example, kidney inability to carry off acids in deranged metalbolism in placenta and uterus, deranged liver function, deranged thyroid function. It was, therefore, readily seen that the simple correction of acidosis would have little or no bearing on the solution of the difficulty so far as pregnancy was concerned. The quick manifestation of acidosis in influenzal infection in pregnancy showed that the highly sensitive metabolism of the pregnant woman was nearer to the danger line than that of the non-pregnant woman. After a careful reading of the many studies made upon acidosis Dr. Foulkrod thought it impossible to say just what it led to in pregnancy. This, however, did not set aside the possibility of preventing such acidosis from occurring in the course of toxemia. In many toxemias of pregnancy, particularly in the presence of a high ammonia elimination, a good prophylactic and curative measure had been found to be the rectal instillation of alkaline antacid solution in combination with glucose. This had a particular bearing in the nausea of pregnancy and other forms of insufficient metabolism. It was certainly true that the alkaline treatment in the early stages of influenzal infection mitigated and sometimes prevented acidosis as seen in the severe epidemic of October, 1918. No dogmatic statements, however, should yet be made.

"Paulist Fever."—There has been a type of continued fever, an endemic affection, in Sao Paulo, Brazil, dating from 1896 and associated with the increase in immigration. It became known as Paulist fever. Recently, according to an abstract in *La Pediatria*, and thanks to the activities of the new Bacteriological Institute, the fever has been shown to be typical typhoid.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago and New York, December 2-19, 1918.

(*Continued from page* 222.)

MATERIA MEDICA AND THERAPEUTICS.

Answer the first six questions; from Questions 7 to 12 choose four.

1. (*a*) Give the source and physical properties of strychnine. (*b*) Discuss the action of strychnine as a heart stimulant.

2. (*a*) Describe three actions of morphine. (*b*) Give the signs of an overdose of opium.

3. Explain the sudden death in the use of ether and chloroform as an anesthetic.

4. (*a*) Give the source of atropine. (*b*) What is the effect of atropine on the heart beat? (*c*) In which disease of the eye has it an important diagnostic significance? (*d*) In which disease of the eye is it contraindicated?

5. Explain the therapeutic effect of sodium salicylate in acute rheumatism.

6. (*a*) Discuss the pharmacologic action of digitalis on the heart muscle. (*b*) Write a prescription containing digitalis for a patient with mitral stenosis and attending dyspnea, visceral congestion, and edema of extremities. Include full direction for the patient and indicate the dose intended.

7. Discuss the use of digitalis in acute (pneumococcic) lobar pneumonia.

8. (*a*) Discuss the therapeutic uses of potassium iodide. (*b*) Write a prescription for the administration of potassium iodide, with full directions for the patient. Indicate the condition for which this is prescribed and the dose intended.

9. (*a*) Discuss the action of cocaine on the central nervous system. (*b*) Describe one therapeutic use of cocaine.

10. Explain the therapeutic effect of quinine in the treatment of malaria, and outline the proper dosage.

11. (*a*) What is tetanus antitoxin? (*b*) Discuss the use of tetanus antitoxin as a prophylactic agent and in actual tetanus.

12. Discuss the therapeutic use of an extract made from the posterior lobe of the pituitary body.

OBSTETRICS AND GYNECOLOGY.

1. Give the minute anatomy of the human ovum, and describe the changes which take place from the time of fecundation until segmentation is complete.

2. Describe the mechanism, including the causes, of internal rotation of the head: (*a*) In a normal vertex presentation. (*b*) In an occiput posterior position.

3. Describe in detail the treatment of eclampsia: (*a*) Preventive treatment, in normal pregnancy. (*b*) Treatment of pre-eclamptic toxemia. (*c*) Treatment after convulsions have developed.

4. Name three distinct varieties of contracted pelvis, and describe the pelvis in each case, giving measurements and diagnosis.

5. What are the indications for the use of the following in obstetrics: (*a*) Anesthetics, and choice. (*b*) Ergot. (*c*) Liquor hypophysis, U. S. P. (*d*) Intrauterine douche. (*e*) Catharties—during pregnancy and the puerperium.

ANSWERS.

MATERIA MEDICA AND THERAPEUTICS.

1. STRYCHNINE. *Source:* Strychnos nux vomica and strychnos ignatia.

Physical properties: Colorless solid occurring as transparent crystals or as white crystalline powder, slightly soluble in alcohol, and almost insoluble in water; it has no odor, and is very bitter to the taste.

Strychnine as a heart stimulant. "Among clinicians the opinion prevails very widely that strychnine is a *cardiac stimulant.* This clinical term does not necessarily imply that the drug stimulates the heart directly; but merely that it improves the pulse. As a

matter of fact, strychnine has no effect whatever on the heart in therapeutic doses with *living animals*. Convulsant doses cause some stimulation of the ventricles. When perfused directly through the *excised* heart, the effects are first stimulant, then depressant; but the necessary concentration could not be maintained *in vivo*."—(Sollmann's *Manual of Pharmacology*.)

2. *Three actions of morphine:* (1) It contracts the pupils; this is due to a central action, for it is not caused when applied locally. It also produces a rise of intraocular pressure. (2) It diminishes pain by its action on the brain and medullary centers. It has no action on the sensory endings or on the peripheral sensory nerves. (3) It checks all the secretions with the exception of the perspiration. In the skin it has a diaphoretic action.

Signs of an overdose of opium: Flushed face, sensation of warmth, drowsiness, pale skin, slowed pulse and respiration, contracted pupils, and sleep. If the dose is large enough, the sleep is profound, the patient cannot be aroused, the reflexes disappear, the skin is covered with a clammy sweat, the body temperature falls, and the respirations and pulse become very slow and irregular.

3. *Sudden death in the use of ether and chloroform as an anesthetic. "Death during the induction of anesthesia:* This is common with chloroform, rarer with ether. The usual sequence of events is sudden suspension of the respiration from acapnia or muscular spasm; the asphyxia leads to cardiac dilatation, vagus stimulation, and finally asphyxial failure of the heart. The failure is especially rapid with *chloroform*, because this adds the direct cardiac action of the drug. In *light* chloroform narcosis the cardiac muscle is hyperexcitable; and any excitement is apt to induce ventricular fibrillation and death (this excitability disappears in *deep* anesthesia). The respiration may resume temporarily after the heart has stopped, but the heart itself cannot usually be revived. Failure of the circulation therefore commonly precedes the final arrest of respiration and is the real cause of death. In the case of *ether*, similar fatalities are rarer, but may occur early or somewhat later—in either case due to faulty administration during incomplete anesthesia. The error may have been committed an hour before actual death. In light ether anesthesia the excitability of the respiratory center is increased. If this state is prolonged by excessively slow, incomplete or intermittent anesthesia (as in throat operations), acapnia results. When the anesthesia deepens and the center becomes depressed, the acapnia (deficiency of CO_2) leads to arrest of the respiration and injury to the heart. Stoppage of respiration by *ether* is less dangerous, because the more vigorous heart generally beats until the respiration has resumed. Experimentally, the heart may also be stopped reflexly by vagus stimulation, but clinically this seems to be exceptional. In any case, the phenomena occur with little warning. The danger signs are sudden dilatation of the pupils, pallor, and change of facial expression. Too high concentration of vapor is the immediate cause of these actions. Fright, excitement, struggling, irregular respiration and idiosyncrasy are contributing factors. Crying in children is especially dangerous. *Death in deep anesthesia* is usually due to paralysis of respiration, generally with more or less involvement of the circulation. With *ether*, the circulation is usually fairly good when the respiration stops. With *chloroform*, there is a progressive fall of blood pressure, then failure of the respiration, and finally cessation of the heart; but the pulse is generally imperceptible before the respiration stops. These late accidents are caused by maintaining the concentration of the vapor too high; and since the paralytic phenomena develop gradually, with ample warning, these deaths are generally due to inexperience of the anesthetist."—(Sollmann's *Manual of Pharmacology*.)

4. ATROPINE. *Source:* Belladonna, stramonium, hyoscyamus, duboisia, and other plants.

Action on heart beat: The rate is increased; this is due to the endings of the vagus being paralyzed, and thus the inhibitory impulses are abolished.

Atropine *has an important diagnostic significance* in iritis.

Atropine *is contraindicated* in glaucoma.

5. The *therapeutic effect of sodium salicylate in acute rheumatism* is believed to be due to its power of relieving pain, and also to a possible germicidal action on the unknown specific organism of the disease.

6. *Action of digitalis on the heart:* "Digitalis given to a living mammal by the mouth usually produces a stronger, slower, and more efficient beat of the heart. Keeping in mind the complicated nervous and muscular arrangement of this organ, we may summarize by saying that the direct cardiac effects are: (1) Stimulation of the cardiac muscle, producing increased amplitude and usually an increase of the rhythm of contraction, and a greater irritability of the tissue. (2) Stimulation of the cardiac inhibitory nervous mechanism by strong direct action on the vagus center, together with weaker local action in the heart ganglia. This produces slowing and greater relaxation of the heart. These two factors, *i e.* the direct muscular effects and the vagus nerve effects, are diametrically opposed to each other, hence many of the characteristics of the heart beat under digitalis in the body are to be interpreted through their algebraic addition. Secondary effects on the heart are produced because of the tremendous rise of blood pressure following the peripheral vasoconstriction. This rise of pressure in itself increases the irritability of the medullary centers, therefore the vagus tone, and produces a mechanical stimulation of the sensory end organs of the depressor nervous mechanism, which Eyster and Hooker have shown to be located in the walls of the aorta."—(Greene's *Handbook of Pharmacology*.)

For mitral stenosis, etc.

℞ Tincturæ digitalis
Elixiris simplicis, āā.....℥iv
Aquæ destillatæ q. s. ad.....℥iij

Misce et signa:—One teaspoonful every four hours.

The dose of digitalis is here 10 minims of the tincture.

7. *Digitalis in acute (pneumococcic) lobar pneumonia:* "If the patient does not die of the acute onslaught of the germ by incombatable toxemia, or by exhaustion from a later general toxemia, or from a migration of the pneumococci to the meninges, his survival or death depends on the ability of his heart to withstand the disease. It has been stated, on the other hand, that the heart muscle is not vitally injured in pneumonia. Respiration ordinarily fails before circulation. The heart in pneumonia may be influenced by digitalis in the same way as in normal persons. The workers in the Rockefeller Institute suggest the use of some form of digitalis as a routine in these cases. They use digipuratum, but any other standardized form available may be satisfactory. Its use should be commenced early so that the patient is partially digitalized when necessity arises. Patients are given 0.5 gm. a day by mouth, if seen early. If, on being seen later, they appear quite ill, 1 gm. may be given. When digitalis effects appear, the drug is discontinued as long as the patient's condition indicates that its use is not necessary."—(Osborne and Fishbein's *Handbook of Therapy*.)

8. *Therapeutic uses of potassium iodide:* (1) In the colloid type of goiter. (2) In various circulatory disorders, as arteriosclerosis, angina pectoris, aneurysm: it relieves the pain, but does not effect a cure. The drug probably brings about an absorption of cellular exudates. (3) In syhpilis, in the late secondary stage and in the third stage; the drug causes absorption of the gummatous formations; it has been suggested that a proteolytic ferment is produced. (4) In actinomycosis, enlarged cervical glands, tuberculosis and leprosy, beneficial results are said to follow the use of this drug. (5) In gout, rheumatism, neuralgia, and asthma, it has been used. (6) It is also said to promote the elimination of lead and mercury.

For the third stage of syphilis:—

℞ Potassii iodidi .....℥j
Tincturæ cinchonæ .....℥j
Aquæ destillatæ q. s. ad.....℥viij

Misce et signa: Take two tablespoonfuls three times a day.

The dose of potassium iodide is (here) about 5 grains three times a day, because 7½ minims of solution is equal to about 5 grains of the iodide.

9. *Action of cocaine on the central nervous system:* "Cocaine is a recognized excitant of the cerebral cortex and the central nervous system. The excitement stage is associated with increased excitability of the cortex accompanied by restlessness, often passing into convulsions in the toxic stage, and ultimately ending in paralysis. The medullary centers are excited, then depressed, shown in the quicker respiration, the slower heartbeat due to central vagus stimulation, and an increase in tone of the vasomotor center. All these stages pass rapidly into depression and paralysis. The spinal cord, after cocaine, likewise exhibits an increase in the irritability of the motor side of that apparatus. Reflexes are therefore increased, and this is true not only for the cord reflexes, but for those reflexes which take place through the brain-stem, and even through the cortex itself. The change in function is due to an increase in the sensitiveness of the nervous elements."—(Greene's *Handbook of Pharmacology.*)

Onc therapeutic use of Cocaine. Cocaine is used as a local anesthetic in minor surgical operations: "the direct application of cocaine abolishes the sensation of pain more or less completely in about five minutes, the anesthesia lasting for about half an hour; the duration increases with the concentration. Solutions of 2 to 5 per cent., or the trace of the powder on the point of a probe, are applied to the surface of mucous membranes, or injected under the skin. Stronger solutions are dangerous and offer no advantage. Application to the surface of the skin is useless, since the drug is not absorbed by this channel. Mucous surfaces, on the other hand, absorb it readily. It is desirable to limit the local circulation, *e.g.*, by a constricting rubber band. The vaso-constrictor action of cocaine may be heightened by the addition of epinephrin (1:10,000 to 1:100,000).—(Sollmann's *Manual of Pharmacology.*)

10. *Quinine in malaria:* "Quinine is most effective in the tertian, less in the quartan, and least in the pernicious malaria. It does not act equally on the parasite in all the stages of its development. The sexual forms are more resistant than the usual asexual. Its strongest action is upon the forms which are just breaking into spores and upon the free-swimming organisms; it is much weaker upon the older segmenting bodies, and least upon the young endoglobular forms. Since the resistant endoglobular forms exist in the blood just before the paroxysm, and their sporulation gives rise to the characteristic chill and fever, and since quinine does not act well upon them, it will not be effectual against the oncoming paroxysm. But if it is given at this time it will be present in the blood when the spores are liberated, and as these are most susceptible to its action, it will kill them and thus prevent the development of the new cycle (providing that the dose has been sufficiently large). It should therefore be given several hours before the expected paroxysm so as to allow time for its absorption. The dose should then be quite large, 1 to 2 grams (given fasting if possible) two to three hours before the expected attack (which will in all probability occur), or 0.3 gram four to five times a day in the interval; 0.5 gram per day should be continued for three months after the last chill. To be effective, the quinine must be administered in solution. Large doses of quinine sulphate in pills or powder are probably largely wasted, since they are not dissolved or absorbed; the sulphate requires 720 parts of water for solution. The hydrochloride is more soluble (1:18) but the bisulphate (1:8.5) or the dihydrochloride is the best. Urgent cases may demand intramuscular injections of quinine dihydrochloride (1 gram in 10 cc.) or of quinine-urea hydrochloride (2 grams in 5 to 10 cc.). Intravenous injections of the hydrochloride have also been used. Concentrations of 1:150 are dangerous; and even lower concentrations should be used with caution, for fear of direct cardiac effects."—(Sollmann's *Manual of Pharmacology*.)

11. *Tetanus antitoxin* is a fluid, having a potency of not less than 100 units per mil, separated from the coagulated blood of the horse, or other large domestic animal, which has been properly immunized against tetanus toxin.—(*U. S. P.*)

"It is prepared in the same manner as diphtheria antitoxin, except that tetanus toxin is used for the immunization. It has a high *protective value* if used early; and it would be desirable to administer it in every suspicious case, but without neglecting thorough disinfection. Its *curative value*, after the symptoms have set in, is doubtful and at best limited. It does not affect the toxin which is fixed in the nerve cells, and could only reach that which is still free or being formed. The *immunizing dose* consists of 1500 units, hypodermically, repeated in a week if the wound continues to suppurate. The wound may also be dressed with dry serum. The protection lasts two to three weeks. With regard to the *curative dosage*, in view of the slow absorption, and the importance of gaining time, hypodermic administration alone is insufficient. Large doses must be introduced by several channels. Park advocates the subdural injection of 3000 to 5000 units, followed by 10,000 to 15,000 units intravenously; the spinal injection is repeated in twenty-four hours, and a hypodermic injection of 10,000 units is given three days later."—(Sollmann's *Manual of Pharmacology.*)

12. "*Extracts of the posterior lobe of the pituitary gland* have a strong stimulant effect on smooth muscle, leading to a considerable and rather persistent vaso-constrictor rise of blood pressure; reflex slowing of the heart; diuresis; augmented contractions of the intestine, uterus and bladder, etc. . . . Therapeutically, extracts have been used hypodermically with success to accelerate labor, to check uterine hemorrhages, and in paresis of the bladder; and with more doubtful results in intestinal paresis and in collapse conditions. Oral administration is practically ineffective." (Sollmann's *Manual of Pharmacology.*

OBSTETRICS AND GYNECOLOGY.

1. "The fully developed *human ovum* is a single cell, more or less spherical in form, about 0.2 mm. (1/25 inch) in diameter, and composed of a yolk, a nucleus, a nucleolus, and two enveloping membranes. The outermost membrane, *Zona radiata* or *Zona pellucida*, in the mature ovum is rather thick and tough, and presents a striated appearance, owing to the presence of numerous minute pore-canals, through which nutrition is supposed to be furnished the ovum. It is derived from the secretions of the ovarian tissues.

"The second, or *Vitelline membrane*, lies in close contact with the yolk from which it is developed, and is a very thin and delicate covering. Between the zona and the second membrane there is a narrow cleft, the *Perivitelline space*, which permits free motion of the ovum within its external covering. The *Yolk* or *Vitellus* is a clear, somewhat granular substance, consisting of yolk-grains (food-yolk or deutoplasm), some fat granules, and protoplasm. The latter is usually increased in amount at one point in the ovum, around the nucleus, and this part is designated the animal pole, while the corresponding opposite point, where the protoplasm is less, is known as the vegetative pole. The *Nucleus* of the ovum, also called *germinal vesicle*, occupies an eccentric position in the egg cell, and is surrounded by a nuclear membrane. A reticulum or network of achromatic threads radiates from the nucleolus through the interior of the nucleus; the meshes of this structure are filled with a clear fluid, the nuclear sap. The *nucleolus* or *germinal spot* is also placed eccentrically in the nucleus, and is largely composed of chromatin." (Jewett's *Practice of Obstetrics.*)

Changes in the ovum following impregnation: "Directly after the formation of the nucleus of segmentation by the fusion of male and female pronucleus the ovum begins to segment. The original mass divides itself into two cells (blastomeres), these into four, and so on until the whole ovum is surrounded by a layer of cells including a group of somewhat larger cells morula, or mulberry mass), and a hollow cavity containing albuminous fluid. This stage of development is called the blastula, or blastodermic vesicle. The cells of the ovum next arrange themselves into a thinned-out, laminated layer around the periphery of the ovum, and another layer just within this, the offspring of the central mass of cells (the ectoderm), and the proliferating central mass itself, the entoderm. Regarding the surface of the ovum, an oval, opaque region may be

observed (the embryonal area), and in the middle of this area a streak of greater opacity appears—in the primitive streak. At the site of this streak a depression next appears—the primitive groove. A microscopic examination of a section through this region now shows the development of a median layer of cells (the mesoderm), made up of cells derived in part from a layer furnished by the ectoderm and by another furnished by the entoderm. In the course of its development the mesoderm develops lateral reduplications and parts into two layers (the parietal and visceral layers) inclosing spaces—the body cavity, or celom. The parietal or somatic layer unites with the ectoderm to form the somatopleure. The visceral or splanchnic layer joins the entoderm to form the splanchnipleure. At the end of the second week the development of the embryo proper begins, by the formation of the neural folds, the neural canal, the chorda dorsalis, o notochord, and the somites, or provertebræ." (Hirst's *Obstetrics.*)

2. *Internal rotation of the head (a) in a normal vertex presentation:* "When the head reaches the pelvic floor the suboccipito-frontal diameter of the head which passed the brim in a direction parallel with the oblique diameter of the pelvis begins to turn till at the moment of expulsion it is nearly parallel with the antero-posterior diameter of the pelvis, the occiput normally swinging to the front. The chief agency in bringing about rotation of the head as it traverses the pelvis is the action of the pelvic floor. The floor of the pelvis may be considered as made up of two lateral halves, each of which slopes downward, inward, and forward. That pole of the fetal head which lands first on one lateral half of the floor glides downward, inward, and forward, and emerges from the outlet beneath the pubic arch. When the head is normally flexed the occipital pole first reaches the floor, and as it descends, is rotated inward to escape under the arch of the pubes. It will be noted that flexion is a prerequisite to normal rotation. It is only when the occipital pole of the head dips lower in the pelvis than the sincipital that anterior rotation of the occiput is likely to prevail. Should the sinciput reach the pelvic floor at the same time as the occiput the former may be rotated forward under the symphysis, the latter going backward into the sacral hollow. The influence of the planes or grooves of the bony pelvis, on which stress has been laid by certain obstetric writers, is of secondary importance in effecting rotation of the head. That the action of the pelvic floor is the principal agency in causing rotation would seem to be sufficiently established by the experiment of Dubois. Dubois showed that when the head of a fetus was pushed through the pelvis of a woman who had died before or immediately after delivery, no matter in what position he placed the occiput, if it struck the pelvic floor in advance of the sinciput, it would turn forward, provided the floor had not been injured by rupture or overstretching. After several repetitions of the experiment the floor became overstretched and the rotation was likely to fail."

(*b*) *In occipitoposterior cases:* "Flexion goes on slowly, and consists in a movement of the occiput downward and inward from its original position near the girdle of contact. Following this movement, the occipital end of the head reaches the sacral segment of the pelvic floor. As a result of this, according to the teaching of Berry Hart, internal rotation is brought about, the occiput being thrown or directed forward until it lies in the middle line anteriorly. The rest of the delivery proceeds as in an occipito-anterior case.

Abnormal Occipito-posterior Cases. (1) In some cases the head does not flex well on entering the brim, owing to a small size of the head. The sinciput reaches the sacral segment of the pelvic floor before the occiput on the opposite side, and as a result, according to Hart's law, it is rotated to the front of the pelvis, the occiput turning into the hollow of the sacrum. Clinically, we always speak of this malrotation as a rotation of the occiput to the back; but in reality, according to Hart, the essential feature is the anterior rotation of the sincipital end of the head. (2) In some cases, owing to the disproportion between the occipital end of the head and that part of the brim in relation to it, flexion is prevented, and the head may enter the brim in an extended position, giving a brow or face presentation. (3) In another set of cases the head may enter the brim poorly flexed, and on reaching the pelvic floor may rotate only partially, remaining fixed in its long diameter, being in the transverse of the pelvic cavity." (Jewett's *Practice of Obstetrics.*)

3. ECLAMPSIA. *Preventive treatment:* Every pregnant woman should be under the observation of a physician; her general health, hygiene, diet, and exercise must be supervised; the urine must be regularly examined, every week or even every day, if necessary; the quantity of urine voided, the amount of solids, and the presence of albumin and casts are to be noted; the woman should report at once any headache, disturbances of vision or digestion, or edema; her blood-pressure should also be observed.

Treatment of pre-eclamptic toxemia: Hot baths, diuretics, calomel or salines, plenty of water to drink, irrigation of the colon, elimination from the diet of meat (the patient should be fed on milk, fish, green vegetables, chicken, etc.), the blood-pressure may be reduced by veratrum, chloral, or nitroglycerin.

Treatment after convulsions have developed: Administration of an anesthetic, and emptying the uterus as promptly and safely as possible, are both indicated.

4. THREE VARIETIES OF CONTRACTED PELVIS (1) *Uniformly contracted pelvis,* in which the pelvis is normal in shape, but all the measurements are proportionately diminished. The condition is diagnosed by careful pelvimetry; all the diameters are reduced, and the ileo-pectineal line is palpated more readily than in normal cases. Frequently the promontory of the sacrum is further back than in normal cases. The oblique diameters are 21 cm. or less.

(2) *Flat rachitic pelvis,* in which the pelvis is thicker, heavier, a little smaller, the sacrum is wider, the brim is kidney-shaped rather than heart-shaped, the true conjugate is less than normal, and the transverse diameter is greater than normal; the iliac bones are everted, and the distance between the anterior superior iliac spines approximates or equals that between the iliac crests. The diagnosis is made from the above description and from the history.

(3) *Funnel-shaped pelvis,* in which the pelvis approaches the male pelvis in shape; at the brim of the pelvis the measurements are about normal; but the outlet is narrow, the coccyx projects forward, and the tuberosities of the ischium are turned inward; the symphysis pubis is deep, and the subpubic angle is more acute. The diagnosis is made by a comparison of the measurements at the inlet and outlet, and by observing the points mentioned.

5. *Anesthetics are used in obstetrics* to lessen suffering produced by labor pains; to lessen the pain attending obstetric operations; to relax the uterus when its rigid contraction interferes with version; to promote dilatation of the os uteri; to reduce excessive nervous excitement which may interfere with progress of early stage of labor; to relieve eclamptic convulsions and mania; in cases of abortion when the finger is being introduced to remove retained secundines; in craniotomy to forestall unpleasant recollections; in cases of uterine inversion to relax the constricting cervix and so facilitate replacement; in bipolar version to lessen pain of introducing the hand into vagina; in precipitate labor to suspend action of voluntary muscles and retard delivery; to dissipate phantom tumors while making a differential diagnosis of pregnancy; in all cutting operations upon the abdomen; and sometimes in sewing up a lacerated perineum.—(King's *Obstetrics.*)

Chloroform is most frequently used, but ether is said to be safer.

Ergot is given after the placenta is born, to favor uterine contraction and retraction; in cases of postpartum hemorrhage; and sometimes in subnivolution.

Liquor hyponhysis, U. S. P., is given in cases of uterine inertia when the cervix is dilated or dilatable.

Intrauterine douches are indicated after all intrauterine manipulations, version, high forceps, embryotomy, postpartum hemorrhage; uterine infection.

Cathartics are indicated during pregnancy in cases of constipation, and also in the threatened eclampsia or toxemia; in the puerperium, in cases of constipation.

THE CLINICAL VALUE OF PRELIMINARY STUDY IN RENAL SURGERY.*

BY A. G. RYTINA, A.B., M.D., F.A.C.S.

BALTIMORE, MD.

PROFESSOR, GENITO-URINARY DISEASES, UNIVERSITY OF MARYLAND, COLLEGE OF PHYSICIANS AND SURGEONS.

SURGERY in recent years has achieved many triumphs. Hardly any branch of this specialty, however, can emulate the results obtained by the modern urologist in renal surgery. The genito-urinary surgeon can explore the kidney, remove or repair it with a mortality of about two per cent. Contrast this with the series of one thousand, one hundred and eighteen (1,118) cases collected and reported by Schmieden in nineteen hundred two (1902), in which nephrectomy was done for various conditions. The operations were performed from eighteen seventy (1870) to 1900, and divided into three decades. The mortality rate in 1870 was 43.9 per cent., in the second ten years it was 26.9 per cent., and in the third ten years it was 17 per cent. These nephrectomies were by the lumbar route. The rate, when done by the abdominal route, was doubly higher, viz., 55 per cent. for the first ten years, 48 per cent. for the second ten years, and 19 per cent. for the third ten years. The average mortality by both routes during these thirty years was 35 per cent. To what is this tremendous improvement in the mortality rate at the present time due? Not to any special improvement in the operative technique or to the manipulative dexterity of the operators, but is mainly due to the careful preliminary study and the application of modern urological methods.

Let us mention briefly what these modern urological methods are. Of the greatest importance is the catheterizing cystoscope; next renal functional tests; then *x*-ray, pyelography; the bismuth and wax-tipped bougie; etc. Before we are justified in subjecting a patient to a kidney operation, several important conditions must be fulfilled. We must know, firstly, if there is another kidney present, for there are a number of cases on record of congenital absence of the kidney. According to Morris, the absence of one kidney occurs once in 2,400 individuals. A more common abnormality is the so called infantile kidney. Nephrectomy in either of these conditions would lead to the death of the patient.

Often in these cases the other kidney undergoes a compensatory hypertrophy and may be even painful, so that the general surgeon who thinks a painful, palpable kidney mass a sufficient explanation for certain symptoms and a sufficient excuse for subjecting the patient to an operation may have a rude awakening. More important, however, in this connection, is the determination of the unilaterality or bilaterality of the affection. I can better illustrate my meaning by citing one or two experiences:

E. had certain toxic symptoms and marked pyuria. The *x*-ray showed two definite shadows in the left kidney. The surgeon in charge of the case refrained from operation only when he was told a previous examination by a urologist revealed a bilateral infection of the kidneys. On examination we also advised against operation, because both kidneys were the seat of an extensive pylonephritis.

S. was first seen by Drs. Beck and Blake, who diagnosed a hypernephroma of the left kidney on account of the presence of a very large left kidney. The combined phthalein output was 15 per cent. We were asked to study this patient in order to see if he was a safe operative risk in view of the low functional output. On examination the patient showed polyuria and slight albumenuria, otherwise urinary findings were negative. The right kidney, too, was slightly palpable. Catheterization of the ureters showed the phthalein output of the left kidney, viz., the one on which operation was contemplated, to have nearly three times the output of the other kidney. The diagnosis of bilateral polycystic kidneys was made and confirmed at the time of the exploratory operation.

It is obvious, that if either of these cases had been nephrectomized, death would have resulted. Another theory of the general surgeon that I would like to explode is the point they mention that you can, if necessary, explore both kidneys and by vision and especially palpation easily detect the one which is the seat of a pathological process. I would like to emphasize, that it is essential to learn prior to operation the condition of the affected kidney, and if this study shows the need for removal of the kidney, then nephrectomy even though surface appearances and feel appear normal. I have within the past few years seen several kidneys exposed, which on exposure looked and felt normal, yet upon bisection after removal showed advanced and extensive tuberculosis.

I would now like to discuss briefly not only the diagnostic, but the conservative importance of Pyelography. Pyleography may be defined as the introduction into the kidney, kidney pelvis, and ureter through the medium of the ureteral catheter some shadow casting substance, and then taking an *x*-ray. By means of it we can often diagnose abnormalities, extopias, as well as pathological changes such as new growths, hydronephrosis, etc. The relative position of a stone within the pelvis and substance of the kidney can often be ascertained without the need therefore of bisecting the kidney, as is often done, and thereby not only conserving renal substance but doing away with the

*An address before Camp Meade medical officers, Merey Hospital, February, 1919.

danger of the serious secondary hemorrhage that so often follows nephrotomy for any cause.

One of the most interesting pyelographic experiences I have had is the following:

C. entered the Mercy Hospital with acute pains in the right side of the abdomen for appendectomy. She was transferred to G. U. service by Dr. McGlannan, who thought the symptoms complained of by patient were due to renal colic. She had had a number of previous attacks. *X*-ray of the kidney and ureter were negative. The urinary examination was also negative. A pyelogram showed the upper ureter region bound to the lower kidney pole. A diagnosis of Dietl's crisis was made, due to inflammatory adhesions binding the upper ureter to the lower kidney pole. At operation the above pathological finding was found, only it was due to an aberrant vein encircling the ureter and not to inflammatory adhesions. Division of the vein and replacing the kidney were sufficient to free the patient from any further attacks of pain

Another great aid at the command of the urologist is the bismuth bougie and the wax-tipped catheter. It is surprising to me how frequently the *x*-ray man will report shadows as suspicions of ureteral stone that are extra ureteral, and still more surprising is the large percentage (30 per cent Baetjer) of ureteral stone which the *x*-ray entirely misses. By means of the wax-tipped and bismuth bougie, in conjunction with the *x*-ray and stereoscope, we can discern with almost certainty the presence or absence of ureteral stone. Every urologist of experience can cite examples confirming this experience.

In conclusion, I would like to submit the results obtained by the Genito-Urinary Department of the Mercy Hospital within the last few years, as a result of the application of these methods. The number of cases studied were 111. Of this number, 40 were kidney or ureter stones; 21 cases of renal tuberculosis; 5 of hydronephrosis; 16 of pyelitis, pyelonephritis, or pyenephrosis; 2 of hypernephroma; 1 of polycystic kidneys; 3 of essential hematuria; 3 of perinephrectic abscess; 1 of ruptured kidney, and 19 miscellaneous kidneys. Of the cases operated upon the writer officiated in 31. The remaining operative cases were operated upon by various general surgeons of the Mercy Hospital staff, and a few surgeons of other hospital staffs. Of the cases operated upon at the Mercy by the general surgeons every one of whom participated in the series one or more times, the correct diagnosis was made in every instance, and there was no mortality. In the same period of time there were operated upon a number of kidney cases which were not subjected to preliminary study. The mortality rate and incorrect diagnoses were extremely high. This feature clinches the point I wish mostly to emphasize, viz., if your cases are not studied carefully before operation, your mortality rate will be high, regardless of the skill of the operators, and the percentage of erroneous diagnoses, often resulting in unnecessary operation, will be even higher.

Let us now take up more in detail some considerations of the various groups of cases studied. The number of stone and ureter cases seen and diagnosed was 40. Of this number, 18 were operated upon surgically. Six were nephrectomized on account of concomitant pyonephrosis, and in the others the stone was removed either by nephrolithotomy or pyelotomy. All of these are alive and free from recurrences as far as we are aware, with the exception of one patient who died of laryngeal tuberculosis about eight months following pyelotomy for two stones in the kidney pelvis. There have been no complications, with the exception of two patients, who developed pyelonephritis of the operated kidney. One of these patients developed a persistent fistula, and on ureter catheterization of this side, the catheter failed to go up beyond one inch, giving rise to the belief that there might be present on this side a stone in the lower end of the ureter, which might be responsible for the persistence of the fistula. The *x*-ray picture of the kidney and ureter on this side since operation shows a suspicious looking shadow at the lower end of the ureter. The phthalein test obtained transvesically showed an extremely low output, with normal elimination on the opposite side. On this account the patient's kidney was removed, and found to be the seat of an extensive infected hydronephrosis. Of the kidney stones operated upon, the *x*-ray diagnosis was found correct in every case.

Five cases of ureter stone near or at the ureter orifice were relieved by endovesical manipulations. Four of these were relieved by injecting olive oil into the ureter beside the stone, and the fifth freed by fulgurating the ureter orifice by means of the fulgurating wire placed over the superior surface of the ureter. It is worthy of note that while all these patients had marked evidence of ureter colic, the *x*-ray was negative in four of them. Results from these experiences show that the *x*-ray is very valuable in the diagnosis of kidney stone, but of little practical value in the diagnosis of ureter stone. For the diagnosis of the latter condition, we must depend practically entirely on the wax-tip bougie.

Kidney Tuberculosis.—The total number of cases in our series is 21. Of these, 13 were operated upon. Of the 8 not operated upon, 3 refused operation, and 5 were denied operation, because it was considered that the lesion was bilateral. In this connection, we have had some other interesting experiences, which have been described in another paper. (See *Annals of Surgery*, March, 1917.) It is worthy of note that the correct diagnosis was made in every case coming to operation, and all patients left the hospital, with the exception of one who was in the third week of a splendid convalescence when he suddenly died of pulmonary embolism. This patient represents the only operative mortality in our entire series. One patient died several months after leaving the hospital of intestinal tuberculosis, and another died a short time after leaving the hospital of pneumonic phthisis. Another died six months later of tuberculous exhaustion. In some the fistula was slow in healing, but finally healed up nicely in every case, with one exception.

Hydronephrosis.—Six cases in our series came under this group. Of these, only 3 were operated upon. In one case nephrectomy was done, because the kidney was practically entirely destroyed. In another case of severe colic pains in the kidney region pyelography showed a slight grade of hydronephrosis, but at the operation nothing could be found to account for these symptoms. The kidney was replaced and stitched to the psoas muscle. Patient obtained complete relief following this procedure. In the other cases, pyelogram showed ureter bound to kidney pelvis which was thought to be ad-

hesions. At operation, however, it was found to be due to an aberrant vein. Relief of pain followed operation, and when patient left the hospital she had some infected urine coming from the kidney which she did not have before the operation. One patient who had marked hydronephrosis refused operation, and the other two did not have sufficient symptoms to warrant operative intervention.

Pyelitis, Pyelonephritis, and *Pyonephrosis.*—Of this group, there were 16 cases. One patient who was admitted to the hospital was markedly septic from double pyelonephritis of pregnancy, and was considerably relieved by pelvic lavage and drainage. She not only went to full term, but has since had a second child without mishap or difficulty. Patient has no symptoms, but her urine still contains much pus.

One of these cases was especially interesting. This patient had a previous nephrectomy, and I was called to see him at the Marine Hospital with a history that patient had not voided any urine for the past five days, and that prior to anuria he was passing considerable pus in his urine. Patient's ureter was catheterized on the side of the remaining kidney, and some thick, purulent material was washed through the catheter, and patient immediately began to pass urine with relief of threatening uremia. Catheter was left in the ureter for about two days, when it was removed. Another patient who was very toxic from bilaterial pyelonephritis was relieved by pelvic lavage, water, and urotropin. Two other patients were cured by water and urotropin alone. One patient had a successful nephrectomy done. Five had double pyelonephritis. No special treatment was given, as it was considered useless. Others were lost sight of.

Essential Hematuria.—Of this type, we have had 3. These patients were promptly relieved by an intrapelvic injection of five per cent silver nitrate. In this connection, it will prove of interest to cite the case of one patient who was thoroughly studied and diagnosed as essential hematuria. Following our practice of *x*-raying every case, the report of our leading Roetgenologist showed a suspicious shadow in the kidney pelvis. We decided to operate on the presumption that if our own diagnosis of essential hematuria was erroneous, we at least were adopting one of the methods of treatment recommended by some for this condition, namely nephrotomy.

At the time of operation there was no stone in the kidney pelvis, and the kidney was split from stem to stern without finding a stone. The kidney was then sewed up, and following operation notwithstanding all efforts to stop bleeding by horse serum, calcium salts, ergot, etc., the patient bled just as much if not more than ever. A five per cent. solution of silver nitrate was now injected into the kidney pelvis through ureter catheter, and the bleeding stopped very promptly, and patient has been free from hematuria ever since.

Polycystic Kidney.—We have only had one case of polycystic kidney. This case has already been discussed above.

Hypernephroma.—Of this condition, there are in our series two cases. One of these was operated upon and got along very well until about six months later, when he died of cerebral metatasis. Another patient was studied who was in an advanced stage of hypernephroma and was markedly cachetic. Operation was advised against in this latter case, but the surgeon disregarded the advice. Patient died within twenty-four hours of shock following the operation by the surgeon in charge of the case.

Perinephritic Abscess.—The number of cases in our series was 3. Correct diagnosis was made in each case before operation, drainage instituted, and prompt relief given in each case.

Ruptured Kidney.—We have only one such case in our series. As this case is one of unusual interest, I will go more or less into detail:

F. B., age twenty-one, foreman in munition plant, single. On November 7, 1918, the patient engaged in a fist fight with a fellow employee. The latter during the scuffle delivered a blow with his fist on the patient's back over the region of the right kidney. The patient at once complained of severe pain, but was able to walk to the office of Dr. W. W. Requardt. Dr. Requardt at once sent him to hospital for observation. Shortly after reaching hospital the patient exhibited evidences of shock, characterized by rapid pulse, and cold, clammy condition of the skin. Examination of back showed a point of tenderness over the region of the right kidney. Urine was negative, with the exception of a few red blood cells microscopically. Diagnosis of ruptured kidney was made, but owing to previous neurotic condition and absence of gross blood in the urine, and the unusual occurrence of a ruptured kidney by a blow from the fist, it was decided to wait a couple of hours before resorting to operative intervention. At the end of this time the patient's condition was greatly aggravated, and his pulse was extremely rapid and weak. He was immediately operated upon. The entire postperitoneal space around the kidney was found filled with clotted blood, and on delivering the kidney it was found to be severely torn, the tear going through the substance of the kidney and extending from the cortex nearly to the pelvis of kidney.

As the patient's condition was desperate, it was thought that time could be saved and further bleeding obviated by removing the kidney, and this was done. Patient, as far as operation and wound were concerned, did splendidly. The accident occurred at the time of the influenza epidemic, and a few days after being in the hospital he developed this disease, which was quite puzzling for a time, as it was thought his temperature might have some connection with the operation. He convalesced from the influenza favorably, however, and left the hospital at the end of twenty-five days fully recovered.

Miscellaneous Kidney.—Under this head are included 11 cases, which were thought to be subjects of some kidney disturbances. On examination by various methods, these cases were proved to have conditions not relating to kidney. For example: One patient in whom diagnosis of hypernephroma was made by ureter catheterization, functional tests, and pyelography, was found to have Banti's disease; another had malignant disease of the cecum, one patient who had infection in the lumbar region was referred for ruptured kidney; one hemorrhage from the posterior urethra thought to be due to kidney tumor; one gangrenous appendix thought to be ureter stone, etc.

Eight cases had symptoms suggesting kidney lesions, but the exact course of the symptoms was not made, or if determined diagnosis was not made either on account of our inability to make same, or because the patient would not continue under observation sufficiently long or refused to undergo further examination.

PROFESSIONAL BUILDING.

THE CRIPPLES OF A COMMUNITY.

A SURVEY OF THE DISABLED CHILDREN AND ADULTS IN CLEVELAND, OHIO, AND A STUDY OF THEIR NEEDS.

By DOUGLAS C. McMURTRIE,

NEW YORK.

DIRECTOR, RED CROSS INSTITUTE FOR CRIPPLED AND DISABLED MEN; PRESIDENT, FEDERATION OF ASSOCIATIONS FOR CRIPPLES.

How many cripples are there in any given community? To what extent have they made their own readjustments and placed themselves beyond the necessity of assistance? What are the needs of the others who have encountered difficulties, educational or economic? An attempt to answer these questions for the city of Cleveland, Ohio, was made in a survey conducted during 1916 by the Welfare Federation of Cleveland. The findings of the study have only just been made public.[1]

No similar survey had ever been attempted in the United States; in fact in this country the cripple had never been considered statistically. The national census had enumerated the blind and the deaf, but had never listed the crippled. Persons who had been interested in the cause of those handicapped by orthopedic disability had known it was always safe to start one more hospital, convalescent home, school, or employment bureau for cripples. Candidates for treatment or training never failed to show up in sufficient numbers. But the full depth of the need had never been plumbed, nor the particular character of the requisite provision fully determined.

There had been several census efforts abroad; notably the monumental enumeration and analysis of the crippled children in Germany, reported upon by Dr. Konrad Biesalski.[2] Another attempt on a much smaller scale was made in 1912 in Birmingham, England.[3] The canvassing of one district of a city was undertaken in 1916 by the Association for the Aid of Crippled Children, of New York.[4]

The "Cleveland Cripple Survey," as it is known, had its genesis in the interest of public spirited citizens of that community in the cause of the crippled child, and the desire to have reliable and scientific guidance in the effort to make further provision for cases of juvenile disability. The survey is much more than a census, for each case was studied to ascertain what light it could throw on the needs of the cripple in general. It was found that cripples themselves might be considered, in some respects, the real authorities on the problem of physical handicap. As the report says, "a man with double club hands and double club feet, with the added disadvantages of a meager education and no medical treatment in his life, but who supports himself and others for nineteen years without any aid, can, if he be a thoughtful person, speak with authority of handicaps."

The first question of moment to be decided in undertaking a survey of cripples is "What constitutes a cripple? How may the word be best defined?" The most satisfactory prior definition was utilized in the Birmingham census, already referred to, and held that a cripple was "a person whose (muscular) movements are so far restricted by accident or disease as to affect his capacity for self-support." It was soon found, however, that the dual criteria, physical and economic, would result in a selective census. Confusion would result from the fact that a given physical disability would in one instance be an economic handicap, but in another instance might have no appreciable effect on earning power. This is the old difficulty encountered by workmen's compensation commissions in endeavoring to translate specific disability into percentage of wage loss. The loss of two fingers is to a professional pianist a serious proposition, while to a salesman the same disability is hardly an inconvenience.

It was also, quite wisely, determined that detailed study of the cases in which being crippled no longer meant being economically handicapped would contribute as largely to the solution of the cripple problem as study of cases in which dependence followed upon physical disability.

The definition on which the survey work was based is set forth in the statement of purpose made by the committee: "To discover the economic and educational needs, capacities, and possibilities of children and adults in Cleveland who are handicapped because they lack the normal use of skeleton or skeletal muscles."

There were located in Cleveland 4,186 cripples of all ages, which, calculated in ratio to total population indicates six cripples to every thousand inhabitants. The age distribution showed 22 per cent. under fifteen years of age, 61 per cent. between the ages of fifteen and sixty, and 17 per cent. sixty years old and over.

In sex distribution 63 per cent. were male and 37 per cent. female. The discrepancy is due to the greater liability of males to accidents. Within the working-age limits there was even more marked disproportion. Among those between fifteen and sixty there were 68 per cent. male and 32 per cent. female.

Classified as to color there were 97 per cent. white as against but 3 per cent. colored. Of the 4,076 white cripples 66 per cent. were native born and 34 per cent. foreign born.

Age at Occurrence of Disability.	Number.	Per Cent. Distribution.
Birth to 4 years	1400	34
5 to 9 years	352	8
10 to 14 years	291	7
15 to 19 years	252	6
20 to 24 years	250	6
25 to 29 years	259	6
30 to 34 years	216	5
35 to 39 years	179	4
40 to 44 years	188	5
45 to 49 years	182	4
50 to 54 years	161	4
55 to 59 years	133	3
60 and over	273	7
Not stated	47	1
Totals	4186	100

One of the first requirements in determination of the needs of cripples is a knowledge of the age periods in which crippling most frequently occurs. That the problem is largely one of the childhood period is shown conclusively by the table which follows. The community is justified, therefore, in concentrating on the surgical treat-

ment and the provision of special educational advantages for crippled children. It is an almost startling fact that 49 per cent. of the total cases covered by the survey became cripples before the age of fifteen, while 34 per cent. developed their handicap before the age of five.

The type of disability, classified in simple terms, is set forth in the following table:

Form of Disability.	Number.	Per Cent. Distribution.
Loss of one hand or arm	188	4
Loss of both hands or arms	6	1
Defect of one hand or arm	499	11
Defect of both hands or arms	42	1
Loss of one foot or leg	466	11
Loss of both feet or legs	27	1
Defect of one foot or leg	1546	37
Defect of both feet or legs	365	9
Loss or defect of one or both arms and one or both legs	332	7
Deformity of body	199	5
Paralysis of body	6	1
Not classified	67	1
Disability of legs or arms or of both and of body	443	11
Totals	4186	100

The causes of disability, according to rather broad classification, were shown as follows:

Main Causes of Disability.	Number.			Per Cent. Distribution.		
	Total.	Male.	Female.	Total.	Male.	Female.
Congenital	301	136	165	7	5	11
Accident in occupation	468	457	11	11	17	1
Other accident	1323	966	357	32	37	23
Infantile paralysis	525	289	236	13	11	15
Other diseases	1437	724	713	34	28	46
Not stated	132	66	66	3	2	4
	4186	2638	1548	100	100	100

The significant feature of this tabulation is that 43 per cent. of the cripples were disabled by accidents—a large proportion of which must be considered as preventable.

In the case of the children represented in the survey it was possible to make more detailed classification, and to secure, in the cases of a considerable proportion, through cooperation of physicians, clinics, hospitals, and parents, confirmation of diagnosis. The following statement shows cause of crippled condition among children under fifteen.

Causes Among Children.	Total.	Per Cent.	Confirmed Medical Diagnosis.	Statement of Family.	Not Stated.
Congenital	149	16	67	82	0
Accident	87	9	2	85	0
Infantile paralysis	382	41	250	132	0
Tubercular bones and joints	139	15	130	9	0
Other diseases*	148	16	99	49	0
Not classified	31	3	0	0	31
All causes	936	100	548	357	31

*Other diseases in order of frequency of occurrence were spastic paraplegia, scoliosis, osteomyelitis, paralysis (obstetrical and other), spinal meningitis, rachitis, spina bifida with hydrocephalus, and unclassified diseases.

The next finding of interest showed that 59 per cent. of the cripples over fifteen years of age were employed. The following table classifies the employed and nonemployed according to type of disability:

Form of Disability.	Number.	
	At Work.	Not at Work.
Loss of hand or arm:		
One	147	37
Both	3	2
Defect of hand or arm:		
One	341	86
Both	20	15
Loss of foot or leg:		
One	314	115
Both	14	13
Defect of foot or leg:		
One	721	389
Both	81	165
Loss or defect of one or both arms and of one or both legs	76	174
Deformity of body	73	53
Paralysis of body	3	2
Not classified	10	27
Disability of arms or legs or of both and of body	109	260
Totals	1912	1338

That such a considerable proportion found employment in the fields of manufacture, transportation, and commerce, is the encouraging demonstration in the table here given:

Occupation.	Number.		Per Cent. Distribution.	
	Male.	Female.	Male.	Female.
Manufacturing and mechanical industries	651	77	49	13
Transportation	192	10	15	2
Trade	201	24	15	4
Public service	65	1	5	1
Professional service	45	16	3	3
Domestic and personal service	80	44	6	7
Clerical occupations	49	21	4	3
Not classified	36	3		
Housewives		400		67
Totals	1319	593	100	100

A more definite idea of the variety of such occupations is given by the following table, of occupations followed by four or more men among Cleveland cripples at work, including all forms of handicap.

Agent	6	Manager	5
Assembler	10	Machinist	11
Barber	7	Machine-hand	4
Bartender	7	Moulder	10
Bench-hand	4	Operator (moving picture machine, etc.)	17
Bookkeeper	13	Packer	4
Bridge-captain or engineer	5	Painter	21
Carpenter	21	Pattern-maker	5
Chauffeur	14	Peddler	6
Cigar-maker	8	Planer	3
Clerk	35	Porter	5
Core-maker	10	Printer	5
Crane-hand	6	Proprietor	39
Delivery-man	9	Punch-press, hand	7
Die-maker	6	Repairman	24
Draftsman	7	Salesman	18
Drill-press operator	12	Sorter	6
Driver	4	Stationary engineer	8
Employer	13	Stock-room hand	4
Elevator-man	39	Street-trade	15
Errand-boy	5	Superintendent	7
Finisher	7	Switchman	5
Fireman	5	Tailor	17
Foreman	22	Teamster	21
Grinder	6	Telephone operator	5
Handy-man	6	Timekeeper	9
Helper	11	Tool-maker	5
Inspector	9	Watchman	25
Janitor	17	Weigher	6
Laborer	67		
Lathe-hand	15		

This list is all the more interesting when viewed in the light of the individual histories which follow it, which reveal what varied occupations are followed by men with the same type of disability. For instance, of three men who had each lost both arms above the elbow, one is a

street beggar, the second makes a small living from peddling from a wagon and guides his horse by keeping the reins about his own neck and shoulders, while the third is a judge in the municipal court, whose story is given later in this article.

Before passing to the general conclusions, one more table may be given, that of the weekly wages earned by these cripples. The considerable number of cases where the wage is not stated is explained by the fact that 400 active housewives were included, and also that the worker sometimes manages or owns the business and does not care to state his earnings. "The lack of exact information on this point is oftener an evidence of high than of low earning capacity."

Weekly Wage.	Crippled Persons Over Fifteen Years of Age.			
	Number.	Per Cent.	Male.	Female.
Under $6	87	4	36	51
$6–$10	180	9	127	53
$10–$15	383	20	351	32
$15–$20	350	18	340	10
$20–$25	107	6	103	4
$25–$30	62	3	61	1
$30–$35	28	1	28	0
$35–$40	9	1—	9	0
$40–$45	7	1—	3	4
$45–$50	3	1—	3	0
Not stated	696	36	258	438
Total	1912	100	1319	593

The personal stories of successful cripples given in this book are remarkable by reason of both their number and contents, and form not the least interesting part of its record. "Occupation studies" give, by means of tables, short life histories of many men and women workers, cripples of various types. "Stories of street operators" (21 in number) throw a much-needed light on this unfortunate class. In many cases they are deserving and could be helped to better things. One of the most inspiring examples among the badly handicapped is that of Dave Moylan, the armless lawyer and judge before-mentioned, formerly a railroad brakeman. His right arm was crushed while he was coupling cars in 1896; in 1904 he lost the other arm while still at railroad work through being run down by a switch engine. Undiscouraged, he got odd jobs whenever he could, and finally decided to study law at night school. Not only had he, while earning his living, to complete the entire law course, but to make up the full four years high school course required by the Ohio law—all in three years. He did it, answering the bar examination questions by writing with a pencil held between his teeth. He is now very successful in his hard-won profession. Successes like these show the danger of generalizing too hastily on the lack of capacity resulting from any given disability, and point to the need of a flexible vocation system for cripples which shall encourage to the utmost individual initiative. Though organization is greatly needed to help cripples, it is better, says this report, never to have organized at all "unless the work is done with an irresistible determination to develop so that the helpable but independent group of cripples will not be converted into a self-conscious class. That the crippled population of Cleveland deserves to have the community make a response to its needs as noble in proportion as its own effort will be discovered by even a slight scrutiny of the story the Survey has to tell."

With this reservation, however, a central bureau, or federation of agencies interested in cripples, representing medical, educational, and industrial aspects, is considered desirable. It should bear in mind the following conclusions reached through the agency of the Survey:

Since a third of the adult cripples became disabled before the age of fifteen, the problem of child welfare is at the root of the whole subject. Child cripples need a combination of medical and educational care, in surroundings which make for the quickest possible recovery. The Massachusetts Hospital School at Canton, of which a full account is given, is considered a very successful example of this kind of work. The authors suggest that the work for crippled children should be met as part of a general, liberal program for prevocational education.

The problem of the crippled adults is a problem of working life. Legislation should be passed adjusting for employer and employee alike all matters of compensation and insurance that now stand in the way of re-employment.

The knowledge gained during the war in the lines of surgery, prosthesis, occupational therapy and vocational education should be widely spread and applied to all cripples, whenever possible.

Provision for industrial training for the competent among the handicapped should form a part of an adequate vocational training for all citizens, under federal or state auspices.

There should be special provision for placement of those who cannot place themselves and for the special employment or home industry of semi-invalid cripples taking some small part in active life.

Propaganda should overcome the prejudices of the public against cripples. "An ambitious mechanic, looking for a real job, finds himself classified with the shoe-string peddler on the street, just because he has the same disability. A man with crutches hears people 'speaking up loud' to him, exactly as they would to a person with smoked glasses or to foreigners whose language they do not understand. These apparently trivial things are in reality signs of a general inability to see the man behind the handicap, and are the very things that make the cripple think he is helpless. They contribute, without doubt, toward idleness among cripples and help create the group of sensitive recluses who only wish to come out after dark and the discouraged workman who keeps his crippled hand well hidden in his pocket."

Most important of all, methods of prevention should be devised, in regard to the accidents of industry, to those of everyday life, and to the ravages of such diseases as infantile paralysis and the tuberculosis of early life. Scientific study along such lines can and must reduce greatly the proportion of accidents in future years.

NOTES ABOUT SOME CASES OF HEART FAILURE.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

Symptoms of heart failure, more or less serious in character, are constantly met with in hospitals and less frequently in private practice. Usually they are connected with some evident valvular defect, acute or chronic. We all know what it means in connection with, or subsequent to an attack of rheumatic fever; also in connection with, or subsequent to a general poisoning of the system by typhoid or eruptive fevers; also, too often after a virulent attack of pneumonia or influenza. These are not the patients I have in mind. Nor, indeed, do I wish to direct attention to the overworked victim of hard manual labor, or to the victim of long-continued excesses in eating or drinking of brandy, whiskey or beer.

I am now having in mind other less serious instances in which the heart is also undoubtedly the immediate important sinning factor, which explains not a few of the symptoms complained of by the patient. There are usually other organs involved, and frequently the blood or the nervous system must be toned up again, if we may hope to obtain lasting good effects from mere diet, rest, and cardiac stimulation. Sometimes our most careful inquiry into the patient's habits and antecedents will leave us for quite a while uncertain as to the precise cause or causes of cardiac failure or inadequacy.

In general terms it is wise in almost all these cases to have in view, mentally, certain probable underlying physical conditions as regards the heart itself aside from the personal influences and differences as to age, occupation, and intercurrent or previous causation.

Now for a few examples of what I have specially in mind. A young man at college, or later, when started in his profession of law, medicine, theology, or business, calls to see us because he feels run down, not up to the mark. We first advise rest, mental or bodily; then we regulate the diet. The physical examination is made carefully, and the blood and urine also looked into. Usually in these cases, even though the examination may be otherwise negative, the heart shows a soft, blowing murmur at the apex, and the pulse is somewhat weak or irregular and shows low tension either to the fingers or to the sphygmomanometer. Here is a case that must have, at least for a time, moderate cardiac stimulation with a suitable drug.

Again, in the case of the young woman of society or the shop girl who is tired and ill fed and too closely confined in stuffy salesrooms. She needs as a rule a laxative pill, a proper iron tonic, but also heart stimulation. The middle aged man or woman, often corpulent, with little or no special cares, and having means and opportunity for relaxation and enjoyment. He, or she, after very little bodily effort, as going upstairs even slowly, suffers from slight dyspnea or palpitations. The pulse is recognized after such exertion as rapid, weak, and fluttering. The heart shows a mitral murmur, soft and blowing, and possibly some enlargement, which, if made out clearly, is due to dilatation. The arteries may possibly show changes and the urine a trace of albumin with casts. Not seldom there are manifest dyspeptic symptoms and the sleep is disturbed, restless. Such patients must eliminate the starches in food, take some helpful carminative or digestive agent, like pepsin or pancreatin, but also, for a while at least, a direct cardiac stimulant. In many of these and the preceding examples a little generous wine at lunch or dinner or a small quantity of good brandy or whiskey helps the digestion and also the heart power and regularity wonderfully. Here again, however, this is not all that is required and we must bring in our purely drug treatment. If an evident nervous element is present, belladonna, valerian, ammonia, with or without sweet spirit of nitre, are essential. In addition, however, we should think of strychnine, nux vomica, digitalis, or strophanthus.

Of course there are other drugs which may be thought of and are used by many. These are caffeine, camphor, and sparteine. Personally, I have learned in later years to rely more upon strophanthus than any other drug as a heart stimulant in all cases of the kind referred to. Small, frequently repeated doses of tincture of digitalis, in tablet form, have unquestionably at times helped me—but even in this form it has numerous objections. It must be closely watched, as it often disagrees with the stomach and increases the tension and spasm of peripheral arteries, which, in those at or past middle life, should not be interfered with if we desire to keep up properly and sufficiently the equal supply of blood to the capillaries. Upon this latter much of the good results we should effect from treatment by a drug depends. Now then, strophanthus, when a good, reliable preparation is used, is unobjectionable as a rule. A little diarrhea is all that I have heard complained of and this is infrequent.

It must be borne in mind, however, that only small doses are required at any one time, and frequency of repetition should depend upon results obtained. A minim or two every two hours, is about right where the heart is notably failing; in other cases from four to six times in twenty-four hours, even at first, is all sufficient.

During the past two years I have adopted sublingual medication with hypodermic tablets of tincture of strophanthus as preferable to swallowing by the mouth. The gastric fluids are apparently antagonistic to the stimulating effects of strophanthus. In the tablet form I make use of sublingually, strophanthus is quite as rapidly effective as if it were given hypodermatically.

I cannot emphasize this important fact too strongly. It is of the greatest value to all practi-

tioners of medicine to adopt it practically, and especially in every emergency case. I should add to the foregoing that latterly I have not obtained as good effects from strophanthus as I did, and I am now advising in bad cases of heart failure an extract of strophanthus in granule form which is made in Paris, France. Unfortunately these granules must be swallowed, as they cannot be readily dissolved sublingually. I have not hitherto tried strophanthin, but I am informed by a prominent physician of Brooklyn, New York, that he has obtained the best effects from its use sublingually in tablet form and in doses of 1 500 grain. The preparation this practitioner makes use of is one made in London, England. The granules of strophanthus and also the tablets of strophanthin can now be obtained in New York City.

I could readily extend the limits of my paper, but I prefer not in view of its utility. In one case I have observed lately in consultation I have been disappointed in the remedial effects of strophanthus. The case was that of a lady of middle age, somewhat corpulent, who after an attack of erythema nodosum, most characteristically marked and with painful and febrile symptoms pointing to an underlying rheumatic dyscrasia, developed a slow pulse, somewhat weak and irregular, and a soft blowing murmur at the mitral orifice. Her temperature then went down below the normal for many days together, with the other symptoms present. She was weak and had marked and obstinate dyspeptic symptoms. In this case tincture of belladonna, given in 5 minim doses three times a day by her ordinary physician, with frequently repeated teaspoonful doses of panopepton, ultimately gave relief to the symptoms, which had caused me much anxiety. I was sorely tempted to try crystallized digitalin, but was prevented from doing so by reason of the slow pulse, combined with the other symptoms. It is true that this patient has normally a slow pulse—ranging about 60 to the minute in times of repose—but as it went to 50 in the minute, associated with the other signs and symptoms mentioned, I acted, I believe, wisely. In such instances a condition approximating that of heart block should be thought of, even though marked head symptoms or convulsive seizures are lacking.

42 West Thirty-seventh Street.

THE MOON AND INSANITY.

By E. H. P. WARD, M.D.,

WHITE PLAINS, N. Y.

That the moon is a cause of insanity is a very old, a very widespread and a very deep-seated belief; but no relationship is obvious in fact nor, so far as I am aware, has any hypothesis ever been suggested that would make it seem reasonable in theory, although the most common name of the disorder is derived from this supposed relationship. It has occurred to me, however, that there may be an indirect relation between the two—a relation no longer as a rule obvious, in our civilization, though it may have been obvious in remote times and may perhaps be more or less so to-day among some races. It seems quite well established that there is a direct relation between disturbances in the *sexual sphere* and nervous disorders, and it remains only to show a relation between sexual activity and the moon. To this end, I suggest the following:

In the first place we must consider that the fundamental characteristics of sexual activity were no doubt established in very remote prehistoric times—times of which we have no record except such as we can piece together from the fragmentary evidence furnished by the study of Philology, of Archæology, of Zoölogy, and of Geology. Man is supposed to have originated in Asia, perhaps in the region now the bed of the Indian Ocean, and to have spread thence to other parts of the world. The whole question is lost in the obscurity of remote ages when the configuration of the continents and islands was probably quite different from what we find it today. Geology of course throws much light on the relative proportions of land and water during the various geological epochs, but we have little definite knowledge as to the relation in time between these geological epochs and the origin and distribution of mankind. It seems probable, however, that the early development of the human race was confined to the Old World, and not until comparatively recent prehistoric times did representatives of the Mongolian and Polynesian branches migrate to North and South America by way of Behring Straits and the islands of the Pacific. Now, when we come to consider the distribution and development of man in the Old World, and his subdivision into races, we get some help in the later stages from History, from Philology, and from Archæology; but in the early stages, when his fundamental animal characteristics were being established, we have to fall back upon Geology and Zoölogy. And Geology can help us only in a general way; there are no fixed dates in Geology, and even if there were we could not correlate a geological period with a definite stage in the distribution and development of man as an animal because we have no measure of time in this case either. So we have to fall back upon Zoölogy, and try to solve the problem with the two factors of Isolation and Environment. In trying to apply the factor of isolation, however, we are again thrown back upon Geology, which helps us only in a general way. So we are forced to depend mainly upon the factor of environment.

As the human race spread over the Old World as it may have existed at the time, it found varying conditions of *climate*, with all that climate implies, and proceeded to adapt itself accordingly. In the *northern regions*, man acquired a light coloring for the same reason that the polar bear is white—simply an example of protective coloration, which enables an animal to hunt for its prey or escape from danger by merging with its background, and especially important in a northern climate, where in winter, the time of greatest need, there would be no natural cover; his nose was modified to warm and moisten the air he breathed; his frame was powerful and vigorous, and his mental qualities such as we associate with the Vikings—they had to be to cope with Nature in her sterner moods. On the other hand, in the tropics man acquired a dusky hue which served to protect him from the direct rays of the sun and, equally important, to render him invisible in the dark depths of the tropical vegetation and especially at night, when he might

find it cooler and more safe for his activities; and his nose would be adapted to breathing the hot, moist air and his mental faculties to a life wherein Nature furnished his food without much effort on his part, but surrounded him with a multitude of enemies. These would represent the two extremes, in neither of which does man as an animal thrive so well. In the frigid regions his life is a constant struggle against the almost overwhelming odds of Nature which affords a living to but a limited number of his kind, although it compels these to be vigorous and fearless and resourceful; whereas in the tropics man may live and multiply but has no incentive to exertion and in fact cannot be active, but has lots of spare time on his hands to dream of better worlds.

In the temperate zone, however, the human animal thrives best and is in his proper element. He is so comfortable that all he needs to be happy is just enough calories to keep him alive; he does not have to dream of better worlds, but simply to devise a philosophy that will enable as many of him as possible to live together contentedly in this world. And the arts of civilization would be born early in such a favorable environment but would not be developed beyond a certain stage because nature would not furnish the necessity which is the mother of invention. All she would require would be a patient industry and a very moderate skill. Furthermore, in the temperate regions nature apparently considered a yellow skin most suitable for protective coloration—a fact that civilized man in his slow wisdom is just beginning to appreciate, as shown by the adoption of the olive drab uniform as most suitable for warfare. The Chinese are a race indigenous in a temperate region and probably the only race that has passed its entire existence in a temperate climate; but here in temperate North America the mixed European race that is developing is perhaps already beginning to react to the climate in the *sallow complexion* and brown hair complained of by some and the *materialistic* ideals against which our moral leaders have constantly to preach. Of course, in the intermediate regions we get the transitional types, such as the negroid aborigines of Australia and some of the islands of the Pacific and also the lowest caste tribes of India; also the dusky Arabs and Egyptians merging into the brunettes of southern Europe. We might have expected a white race in Siberia as well as in northern Europe; but the land in Siberia may have been submerged at this period, thus making the isolation of China practically complete with the ocean and inaccessible mountain ranges almost surrounding it except to the south, where the Mongolian type merges with the Negroid.

The question arises why we do not in historic times find representatives of the yellow race in temperate Europe. There are several possible explanations. For one thing, temperate Europe may have been under water; or if not submerged, a yellow race may have developed there and been destroyed or driven eastward by its subsequent submersion. The Basques of the Pyrenees may represent the survivors—they are considered unrelated to the other European races of historical times and some have believed them to be of Mongolian type; similarly with the Finns. There are found in historic times numerous representatives of the yellow race in central Asia, but whether they are indigenous there or came westward from China or were driven eastward out of central Europe is uncertain. The Eskimos are probably representatives of the yellow race that have in comparatively recent times migrated to their present habitat around the Arctic Ocean. The Black race is indigenous in central and south Africa, where its isolation has been almost complete owing to being surrounded by water and deserts; and presents a perfect example of the reaction of man to his environment.

Now we come to the White or Aryan race, which presents great difficulties. It may be because its isolation has not been so complete as that of the Yellow and Black races, or because it has been more restless and enterprising, or possibly it was driven to migrate by geological changes; but, in any case, at the dawn of history we find it extending over Europe and parts of northern Africa and western Asia and southeast into India. It is supposed to have spread from an original home in the mountainous regions of the Caucasus, some of its members having migrated to Persia and India as well as to the coasts and islands of the Mediterranean, and others into Europe, where the successive waves formed the tribes of Celts, Teutons, Slavs, Latins, and Greeks. This supposition is based largely on the evidence of Philology, that comparative study of languages in which, as Voltaire remarked, the vowels count for nothing and the consonants for very little. But the general character of the languages is the same and many of the words have common roots, and it seems quite certain that these members of the White race had a common origin. But the affinity between the languages of the groups in southern Europe—the Latins and the Greeks—is much more pronounced than between them and the northern groups—the Teutons and Scandinavians. Possibly temperate Europe was submerged to a considerable extent when the Aryan race first overran the continent and the groups to the northward were for a long period cut off from those to the south. This would account for the divergence of speech and tend to accentuate by isolation the physical characters of the blonds in the north of Europe and the brunettes in the south. Possibly too the land area in northern Europe may have been more extensive then and the climate milder. Then, at a later period, when central Europe emerged again, subsidence of the land may have occurred in the north with an intensification of the cold (this may have been when the herds of mammoths were frozen in the snow and ice). Thus we might assume that the blond peoples of the north would be driven southward and an intermingling would take place between the blonds and brunettes. We know that central Europe has been under water and if we can assume that the period of its submersion bore some such relation to the development of man as is suggested above we avoid the difficulty of explaining how the blond and brunette types could have become so distinct while developing side by side, as we find them at the dawn of history when they were already making inroads the one upon the other and becoming intermingled. In any case, this process of intermingling of the blond and brunette types of the white race in Europe has

been going on ever since the dawn of history, so that most of the races of Europe and their descendants in America and other parts of the world represent a mixture in varying proportions of the blond and brunette types, with a mixture of the corresponding physical and mental characteristics of these types. Thus what we are pleased to consider the civilized world is made up almost wholly of these mixed types, and the restless activity and energy of our civilization might be considered as due to an instability resulting from the commingling in varying proportions of these diverse elements. Some investigators, notably Dr. David Orr Edson, have made quite a study of the question of the varying degrees of blondness and brunetteness in the individual, as shown by pigmentation (especially of the eyes) and facial proportions, and have thrown a great deal of light on many different phases of the relation of the individual to his environment in our civilization.

Now that we have considered these fundamental principles, we can take up the question of sexual activity and its relation to the moon. No doubt in primitive man sexual activity—the act of mating—took place at night. Hence degrees of light or darkness affecting it would depend upon the moon. Probably in the torrid regions, surrounded by lurking enemies of his own and other species, the brunette would be safer in the act of mating when the darkness was as complete as possible—that is, in the dark of the moon. If so, by a process of natural selection, sexual activity in the brunette races would become periodical at intervals of a lunar month and would occur in the dark of the moon. With the blonds in the northern regions, on the other hand, mating might reasonably be assumed to take place most favorably in the moonlight; absolute darkness would not be necessary for safety where lurking enemies were not numerous and moonlight might be a positive advantage in escaping from such enemies as there were, such as wolves. If so, natural selection would bring it about that sexual activity would take place at intervals of a lunar month, and at the full moon. Now, when the blond and brunette types intermingled, the periodicity and the interval of a lunar month would probably be retained, as common to both; but the phase of the moon at which sexual activity would occur would vary with different individuals according to the proportion of blondness and brunetteness in their make-up—the more nearly the individual approached to the pure blond type, the more nearly sexual activity would tend to occur at the full moon, and vice versa. Especially in the more conservative female of the species would this periodicity be retained, although perhaps it is already beginning to be less definite in our artificial civilization where it no longer has any definite relation to environment; whereas in the polygamous male, mating with a number of females at different periods, even the periodicity would be lost or submerged and sexual activity become subject to stimulation. Thus would arise the conditions as we find them in our civilization today.

This hypothesis appears to me to be reasonable and likely, but I merely suggest it here as a possibility and leave its testing to those investigators who may have better facilities and more first-hand knowledge of the facts. Much of it, of course, is based on assumed conditions in times so remote and obscure that perhaps we cannot hope ever to ascertain the exact facts. But there are races today, perhaps, pure blond and pure brunette; among them, does sexual activity occur at the full moon and in the dark of the moon, respectively? I do not know; perhaps some one else may. I understand, however, that in the romantic literature of the blond races the full moon plays an almost unfailing part in the love scenes, apparently being inseparably associated with mating; this would bear out my hypothesis. While, on the other hand, the French, a mixed blond and brunette race for whom no particular phase of the moon would be associated with mating—least of all the full moon as they are more brunette than blond—never tire of ridiculing the German novelists whose idea of romance they consider is limited to an introduction of the full moon into the picture.

So much for the relation of the moon to sexual activity—once the determining factor as to the time and frequency of its occurrence, but no longer so in the mixed blond and brunette type in our civilization excepting in so far as the periodicity originally dependent upon it has become implanted in the fundamental animal nature of man, and especially of woman. Now, if nervous disorders and insanity are due, in part at least, to disordered sexual activity, they would naturally be manifested most strongly at the normal period of sexual activity—i. e., at full moon in a blond race and in the dark of the moon in a brunette race; and occurring thus at a definite phase of the moon, primitive man would naturally conclude that the moon was the cause and thus it would be handed down in folklore and tradition; and such I believe to be the basis of this conviction which is still widely held today. Possibly today in Iceland and Scandinavia sexual activity occurs at full moon and perhaps outbreaks of nervous disorders are also more prevalent then; and in equatorial Africa among the natives, in the dark of the moon. If any facts along these lines have been published, I do not know of them, but some one else may or may have first-hand knowledge of them. In any case, I submit the hypothesis for what it may be worth.

North Street and Ward's Lane.

THE PHYSIOPSYCHIC CURE OF A DRUG HABITUÉ.

By J. C. DENSTEN, Ph.D., M.D.,

SCRANTON, PA.

Habit has been defined as "a regular and fixed mode of action whether physical or mental." An habitué is one who is an habitual frequenter of certain places which afford entertainment of a satisfying nature, hence we have the drug habitué, returning habitually to the place where his appetite may be appeased by obtaining some sought-for drug.

In the treatment of a drug habitué we should direct our therapy to apply to the mental as well as to the physical, both subjectively and objectively. In order to hope for a cure, we must control the environment of the addict *absolutely* and have full control of every intake.

While there are many and varied methods of cure, proposed and practised in camouflaging the drug habitué, the most absurd to my mind is the gradual reduction method. It insures the return of the patient for his daily supply and insures a daily income to the physician, and when the habitué reaches the minimum of allowance he will go to another physician and begin all over again. He will work two or more physicians simultaneously if possible and will peddle the surplus, if any remains above personal demands. It becomes axiomatic that a drug addict is not cured so long as he or she indulges in the habit-forming drug in even an infinitesimal allowance. It also becomes extremely farcical even to attempt this or any method of cure directed from the practising physician's office.

We have had more than four years of the Harrison Antinarcotic Law and the Federal Government has endeavored to provide a method of cure for the drug habitué, but statistics prove that few if any cures have resulted under that law and that there are at present more drug habit addicts in the United States than before its passage. It has cost the Government thousands of dollars per annum to provide an army of inspectors to prosecute the suspected violators of this law, who prove to be not the users of the drug but physicians and druggists and persons who previous to the passage of the law were considered honest and respectable citizens of the United States.

A law that encourages crime or offers temptation or suggestion to any inoffensive class of individuals, whether professional or otherwise, is an objectionable and vicious law and should be repealed or amended to obviate its penal influence. Better that one honest and respected person should remain honest and respected than that a dozen knaves should be reformed.

The present Harrison Antinarcotic Law has been weighed in the balance and found wanting. It has no record of cures; has given no relief or hope to the drug habitué; has branded respected members of the medical profession with the iron of criminal suspicion; has made paupers, prostitutes, and vagrants of many drug habitués, by raising the price of the drug beyond his or her means to obtain honestly; has thrown suspicion on honest practitioners of medicine and placed under the ban the very name of morphine, cocaine, and heroin, drugs which were and still are a blessing to suffering humanity, when applied in reason and only when indicated therapeutically.

We would not complain were the law a benefit to the curative end of an habitué; but when the very aim and fire have been deflected from the main object, we can but protest the more when we ourselves are brought within its range and made "to suffer the slings and arrows of outrageous fortune" by the law's misaim.

For a long time the failure of the present Federal law to become effective in benefiting and curing the drug habitué has been noticeable and State legislatures have endeavored to add some adjunctive law, in hope of solving the puzzle. But the State procedure seems to offer no more intelligence toward a solution. If one be fishing with minnows without results, would one become more successful if he changed his bait from minnows to shrimps? Not if fishing for the same kind of fish were his object.

In conversation with a Federal inspector, he took the writer to task for asserting in a previous article on the Harrison Antinarcotic Law, that the present law was "for revenue only." He begged to differ with me, saying "That the present law did not afford any surplus to the Government, but just enough to pay the expenses for collecting and adjusting." Which was equivalent to confirming my statement, "For revenue only." Now there will be quite an acknowledged "revenue," for they have trebled the cost of a license from one to three dollars a year since January 1, 1919. Just how it is going to benefit the drug habitué remains to be seen. The promises of the law to benefit the "addict" still remain promised. The excuse now is that "their expenses have increased." We are of the same opinion since we observed the line-up in New York City by the army of Federal inspectors, sleuths, and gumshoe men. But the joker still remains, viz., they penalize everybody connected but the "addict."

The demand for any article regulates and determines its value. The great and increased demand for narcotic drugs since the passage of the Harrison Antinarcotic Law would insure *a priori* an increase in price, and since the demand regulates the supply it would follow *a priori* that an increased demand would increase the supply. This is the condition of affairs in the United States since the antinarcotic law has been in effect.

The Harrison law needs to be intelligently amended or else repealed and an entirely new law enacted. There is need of a Federal law indorsed and ratified by each State. There should be a law which will compel every drug addict to enter an institution provided and supported by the State for the treatment and cure of these unfortunates, and compelled to remain until cured or dead. A drug addict if not cured or not receiving sufficient elements of nutrition by some drug containing the same food value, *not narcotic*, or sufficient culinary food, will go insane or die if not allowed the drug.

It would follow from a compulsory treatment law that within a limit of three years there would not remain one drug addict within the States. They would have all been cured or dead. The underworld would have gone out of business for want of patronage and the number of new converts would have become nil. The morals of every community would benefit by the object lessons and exposure of the addicts who will have been compelled to take treatment.

So what good effect has this present Harrison Antinarcotic Law? As it stands it has proved itself for revenue only. Meanwhile we are contributing our three dollars yearly to support and maintain a small army of inspectors, sleuths, and gum-shoe men who, in ignorance of our difficulties, necessities, conditions, environments, and privileges, seek to confirm their suspicions of us and stand ready and seemingly anxious to brand us as criminals, and the dear addicts, for whose benefit this law was enacted, are still searching for the promised benefit, having been initiated into the inner circle of the underworld supply, whence the drug habitué emerges laden with addiction commensurate with the size of his roll.

In the treatment of the drug addict there will be sore need of the services of a psychologist. The mental vagaries accompanying these addicts are

many and varied. The subject must have both mental and physical exercise with light and entertaining work. Idleness should not be allowed. Sleep is a great factor in the reconstruction of cell virility. The drug should be instantaneously and absolutely withdrawn and a substitute drug or drugs with forced culinary food pushed to the limit. These substitute drugs must contain the same elements of nutrition, *not narcotic*, as contained in the habit-forming drug, such as quinine, strychnine, atropine sulphate, hyoscyamine, etc., given hypodermatically or otherwise as often as necessary to furnish the food value to support and feed the patient.

In the cure of a drug addict the physician should be at all times master of the situation. He should be well versed in physiological chemistry and materia medica. It becomes a question of immunization; of mathematical equations; of keeping the vitality and mentality of the patient above the desire for the narcotic induced previously by its absence. This may be accomplished by feeding the elements of nutrition and food found in strychnine sulphate ($(C_{21}H_{22}N_2O_2)_2H_2SO_4 + 5H_2O$) which contains carbon, hydrogen, oxygen, and nitrogen, the same elements as are contained in cocaine ($C_{17}H_{21}NO_4$), or morphine ($C_{17}H_{19}NO_3 + H_2O$), or heroin ($C_{17}H_{17}NO + C_2H_2O_2$)$_2$. Strychnine sulphate may be given in large doses (Gr. 1/20 to Gr. 1/15 with impunity. Strychnine is not cumulative in its action and releases its maximum effect within two hours. This is an ideal drug to substitute for the narcotic drug in the treatment of addiction, with intent to cure, both before and after absolute withdrawal of the narcotic. Other drugs may be studied with this end in view. Strychnine sulphate contains both carbohydrate and protein and hence remains tissue building, being a nitrogenous food. Culinary food should be pushed to the limit and the drug food be gradually withdrawn as the patient becomes strong.

The drug addict should remain under the law after cure. A penal clause making it a misdemeanor for anyone to sell, offer, or give the drug to a previous habitué. The institution should remain an alma mater and refuge to any and all previous inmates when they are destitute.

If a Federal law were enacted establishing institutions or sanatoria throughout the various States for the care and cure of the drug habitué containing a compulsory clause of committal, appointing one or more physicians in each community or district whose certificate will act as a commitment for the drug addict either in Federal, State or private sanatoria, and thus withdraw from the general practitioner all responsibility for prescribing in an attempt to cure the drug addict, it would be distributing charity to the physician, the druggist, and the addict very different from the existing conditions under the present antinarcotic laws, both Federal and State.

The physician and druggist would then willingly aid the national government and State in detecting and committing for treatment the drug habitué and thus of themselves become an army of one hundred thousand or more willing workers in support of the law without fee, and thus abolish the present expenses of sleuths and prescription meddlers.

Under such a procedure and law there would be no need for narcotic prescriptions or narcotic dispensing and thus would be re-established the respect of both physician and druggist. But the great superlative benefit would lie in the endeavor of the law to aid to its uttermost the drug addict in a proffered cure with reasonable chance of success.

There are none so low but they long for reverence. None so weak but they can absorb strength. Shall we, being stronger, withhold our strength and support, while politicians rule us and obtain temporal benefit at our moral expense?

116 Adams Avenue.

REPORT OF A CASE OF ACUTE GANGRENOUS PANCREATITIS.

By M. D. BLOOMFIELD, M.D.,

PHILADELPHIA, PA.

My object in reporting the following case is to place on record the occurrence of this malady and further to illustrate how confusing the symptomatology appears. Several men of exceilent diagnostic ability had been consulted, but the correct diagnosis had not been made in this case until the patient was opened up by the surgeon.

The patient was a male, fifty-four years of age, milk dealer, father of two adult boys; the family and personal histories were negative in every respect as to any light which might be thrown upon the present illness. This gentleman while on a visit to a creditor of his, in order to meet his appointment at the precise hour, quickly partook of a luncheon consisting of a glass of milk and a small piece of apple pie. He ate this rather quickly. One-half hour later was seized with pain in the vicinity of the gall-bladder, radiating to the mid-spine. There was no vomiting and the patient attended to his business as usual. The same evening he took two soap enemas and a bottle of magnesium citrate. The pain the next morning was severe, located in the vicinity of the appendix now, but not incapacitating the patient from attending to his usual duties at the store. He had not consulted any medical man as yet. He continued all day at work despite his distress. On the third day he called in a neighborhood physician, who diagnosed his case as appendicitis, ordered ice to the abdomen, abstinence from all solid food, and an opiate. The pain still continued in this region. On the fifth day a surgeon was called into consultation who was positive he was dealing with a surgical gall-bladder, but not necessitating any immediate operation. The same evening, the family states, the patient vomited what looked to them as pure bile, with constant retching until the following morning. I saw the patient at 6 A.M. on the sixth day of his illness. He presented the following clinical history: Skin yellowish, cold, and clammy; eyes showed pupils dilated, sclera and conjuctiva slightly icteric; tongue brownish and furred, the odor of the breath was meaty in character; the patient was in constant fear of death and continuously wept. His superficial and deep reflexes were exaggerated. The stool was clay colored and had the natural aroma; urine showed a trace of albumin, no glocose or pentose, specific gravity 1,045. Pulse rapid, thin, 105; respiration 26, temperature 97.6°. Surgeon No. 3 was hastily called upon my advice and this gentleman was sure he was dealing with a case of ruptured or perforated gastric ulcer, probably malignant, and advised immediate operation. The patient's abdomen was rigid, with greatest tenderness over McBurney's point. There was constant retching and vomiting of bile-colored fluid. While arrangements were being made to transport this patient to the hospital, the family had summoned surgeon No. 4, who arrived a few minutes before the patient was brought to the hospital, and he was positive he was dealing with a case of gangrenous appendix, peritonitis, and probable cholelithiasis. It was now 5.45 P.M. on the

sixth day of the illness. The patient was slightly cyanotic, moaning, and retching continuously. Despite the various opinions offered by our consultants, I felt one thing certain and that was that the patient should be opened up immediately. I called up Dr. James A. Kelley of St. Joseph's Hospital, explained to him the circumstances of this case, and he promptly ordered the operating room prepared; the ambulance was rushed to the home of the patient, and within ten minutes of his arrival at the hospital was on the operating table. A large median incision was made into the very rigid abdomen, under nitrous oxide anesthesia. On opening the abdominal cavity a foul-smelling, brownish, and blood-tinged fluid gushed from the retracted surfaces. With a great deal of difficulty, the cavity was sufficiently mopped to permit of proper exploration; the appendix was found in its normal site, with no visible pathology; gall-bladder and duodenum likewise normal. Suddenly there spurted small pieces of lymphoid tissue and fat-necrosed particles of tissue, again accompanied by a large quantity of brownish fluid. When this was dried away, the pancreas was found; the head of this organ was completely necrosed for about 4½ inches. Hemorrhagic areas and numerous minute necrotic areas studded this organ along its entire course; drainage was instituted after thorough ligation; the wound was safely sutured, and the patient was returned to bed fifteen minutes after being operated on. All the necessary postoperative care was administered, but the patient died ten hours after his admission to the hospital.

2008 N. Park Avenue.

Relations Between Influenza and Equine Infections.—Micheleau has no doubt of the relationship between the present pandemic of grippe and a dermatosis of horses which is associated with foci of bronchopneumonia. The skin affection is really a cellulitis, a phlegmonlike affection, which causes the animal to be spoken of as anarascous. It occurred to him to test a serum from the blood of such horses on human beings with influenza, but the existing regulations make it necessary to obtain the sanction of the Academy of Medicine and Pasteur Institute. The latter, which prepares all serums used, had no resources for manufacture of the one in question.—*Journal de médecine de Bordeaux.*

Diffusion of Pandemic Influenza.—With the exception of the recent pandemic the diffusion of influenza has always begun in Russia, reaching the Atlantic and Mediterranean in a few months by the main travel routes. There is, therefore, some reason to anticipate the discovery that the epidemic of 1918 had the same origin. Heretofore Italy has been invaded either from the North or through its ports, in the latter case doubtless from the Levant, which in turn had received the disease from Russia. Ilvento is inclined to believe that the recent pandemic entered Italy by the Swiss frontier. Apparent contradictions in chronology may be explained by the presence of small foci which remain latent until suitable conditions for diffusion appear. There is no reason to doubt that pandemic influenza is essentially benign. The author makes no attempt to distinguish between this affection and endemic winter grippe.—*Annali d'Igiene.*

On the Spanish Grippe.—Spengler has written a book on this subject which is reviewed by Galli-Valerio in the *Correspondenz-Blatt für Schweizer Aerzte.* The work will be a serial, issued in separate fasciculi and volumes. At present the first fasciculus is on the market. The author insists that the Spanish disease is not in any sense the influenza of 1889. It is due to a specific organism which, of course, is not that of Pfeiffer. It resembles considerably the *B. pestis* in its polar coloration and pleomorphism. The reviewer here takes pointed issue with the author and emphasizes the great number of differences between Spengler's bacillus and the *B. pestis.* The two points of resemblance are shared by numerous other organisms and signify little. The criticism of the reviewer invalidates all of the conclusions of the author, which are based on the same, in reference to acquired immunity and prophylactic vaccination. Just what Spengler's bacillus is the reviewer does not attempt to state.

Medical and Surgical Lessons of the War.

PSEUDARTHROSES OF THE HUMERUS CONSECUTIVE TO WAR WOUNDS.*

By Dr. CHARLES DUJARIER,
PARIS, FRANCE.
SURGEON TO THE HOSPITALS.

Anatomical Types.—We may distinguish two groups of pseudarthroses of the humerus, namely, closed pseudarthroses and pseudarthroses following gunshot fractures.

1. Closed pseudarthroses follow a fall or some other injury. They are not accompanied by loss of bony substance, but are due to the interposition of muscular tissue. In this group we may also include the seton wounds by bullet in which the projectile has produced a fracture in grazing the bone. The seton wounds easily heal without suppuration. There is no loss of substance and the course is exactly analogous to that of a simple fracture. This group is not of much importance since of the thirty-eight cases of pseudarthroses which I have had occasion to operate on during the war I find only two which could be included in this group. These were the pseudarthroses which we usually saw before the war. The treatment consists in raising the interposed muscular tissue, reducing the fracture, and maintaining it by a screw plate. That is what I did in my two cases and the fracture healed without incident.

2. Quite different is the group of pseudarthroses due to comminuted fracture produced by projectiles. Here, as a general rule, there has been a loss of substance as well as infection. According as one or the other of these two factors predominates we have the following two schematic types:

(*a*) When the loss of substance has been considerable the arm presents a characteristic appearance. It has an hour-glass form, a narrowing marking the bony defect. There is formed there a sort of cutaneous tube, furrowed by cicatrices in which pass the muscles, vessels, and nerves. The arm is swinging and can be twisted in all directions, and although the forearm and hand are normal the limb is useless. The radiograph shows the two extremities terminating in a point and sometimes intermediate fragments mark the place previously occupied by the shaft of the bone.

(*b*) In the second type it is the suppuration especially which is the cause of the pseudarthrosis, and the separation between the two fragments is slight. Sometimes even the fragments touch and in a radiograph the pseudarthrosis is not apparent. In this form the arm is less flail-like than in the preceding. A sort of callus is formed and in some cases there is only a slight degree of movement at the level of the solution of continuity of the bone. The particular characteristic of this form is the irregularity of the fragments. They are swollen, with an indefinite contour, and there are often intermediate fragments, variable as to form, volume, and number. The inflamed bone has reacted exuberantly, but the new bone is of poor quality.

*This work is based on thirty-eight onerations done by me at Rennes, where I was chief of the Surgical Sector from 1916 to 1918.

The osteophytes grow out in various directions; often one sees many irregular osseous spines while cicatricial fibrous tissue envelopes the whole and adheres closely to it. This renders difficult, long,

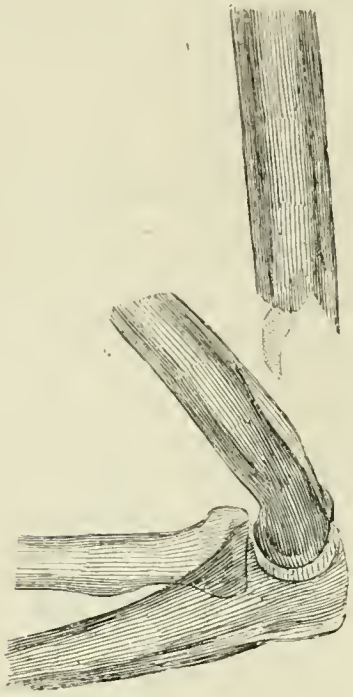

Fig. 1.—Simple closed pseudarthrosis.

and fatiguing any operation undertaken to free the two extremities.

I would note finally an intermediate type, namely, one in which the loss of substance has been considerable but regeneration has occurred. The osseous band which reunites the fragments is, however, usually incomplete, and when it is complete it is fragile and flexible. I have often observed in these cases fractures reproduced as a result of an effort, of a sudden movement, or of a fall. What is necessary to do in these cases is to strengthen the uniting band or to complete the work of spontaneous healing. The osteoperiosteal graft is here especially indicated.

In addition to the findings already noted, the radiograph when closely studied gives other useful details. (1) It will show osteoporosis of variable extent. Sometimes this diminishes as we recede from the fracture and sometimes it involves almost the whole of one or both bony fragments. This occurs especially in the smaller fragments of a pseudarthrosis near the joint. The decalcification of the smaller fragment is such that the raspatory can be pushed through it without difficulty, and it is indispensable in cases of this kind to treat the fragment gently if one would not reduce it to pulp. We must especially avoid trying to fix it with screw plates.

It is interesting to follow the osteoporosis in these cases of pseudarthrosis in serial radiographs. After the wound it progresses for a variable time, the bone becoming paler and almost transparent. On the other hand, when consolidation is obtained the bone again becomes opaque in proportion as it resumes its proper function. (2) Sometimes we note sequestra, some superficial and others central, surrounded by a clear zone of rarefying osteitis. These sequestra may exist in pseudarthroses in which there have been no fistulas for a long time. We shall return to these later. (3) Finally we often see the projectiles, whether of large size, such as bullets or shell fragments, or metallic dust disseminated throughout a more or less extensive zone.

Lesions of the Neighboring Parts.—1. The adjacent *articulations* are often stiffened but in none of my cases have I observed true ankylosis. I have sometimes feared this ankylosis, for nothing is so difficult as to restore the mobility of an articulation in certain cases of juxta-articular pseudarthrosis. It is often only in the course of the operation, in seizing the smaller fragment directly with the bone forceps that one may be sure of its mobility.

2. *Muscles.*—These are always injured—sometimes destroyed, sometimes invaded by cicatricial tissue. In the course of the operation, thanks to the shortening produced by the osseous suture, we can sometimes remedy these defects either by extirpating the fibrous blocks or by bringing together two healthy parts of the same muscle. But one must recognize the fact that these muscle lesions are often irreparable and that it is to them that is due the greater part of the partial inability that remains after consolidation of the bone.

3. *Arteries.*—In none of my cases did I observe any destruction of the brachial artery; that is to say, this lesion is rare. But I would say a word regarding the nutrient artery of the bone to which has been attributed a preponderating rôle in the evolution of pseudarthroses. In every case, indeed,

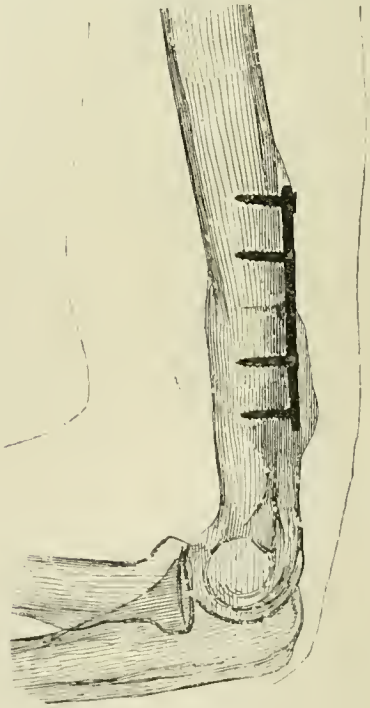

Fig. 2.—Fracture shown in Fig. 1, treated by a screw plate, consolidation in 48 days.

one of the branches must be destroyed, and often it is the trunk itself of this artery which is divided. I do not know what rôle this lesion plays in producing the marked osteoporosis of the fragments; but in any case it in no way hinders the production of

bony callus, even in the juxta-articular pseudarthroses.

4. *Nerves.*—Among the nerves it is especially the radial which is apt to be injured. In none of my personal cases have I noted important or serious

Fig. 3.—Pseudarthrosis with incomplete regeneration of bone.

lesions of the median or ulnar; whereas in seven cases, that is to say in almost one case in five, I have found the radial divided. This is a grave complication. I had even believed before the war that a lesion of the radial nerve was in itself a sufficient cause of failure in the treatment of pseudarthrosis of the humerus. In three cases of double lesion I had indeed failed to obtain bony consolidation. In reality, however, this belief was false, for of my seven cases of double lesion I obtained bony union in six. Besides division of the radial nerve we may also sometimes meet with its compression. This nerve is very often caught in the fibrous tissue passing between the fragments, and we shall see that one of the chief difficulties during operation is to avoid injuring the nerve during the liberation of the fragments.

5. *Skin.*—The cutaneous lesions are important for they may interfere with the treatment in one of two different ways. When there are depressed cicatrices adherent to the deeper tissues and sometimes even to the bone, we must either free them or excise them. I have never been obliged to perform an autoplastic operation, for following the operation, the member being more or less shortened, there has always been sufficient skin tissue to retain the sutures.

In other cases there are fistulæ. These are due to the presence of osteitis and their existence, as we shall see below, offers a problem the solution of which is very delicate, that is to say the time of interference.

Treatment.—Before entering upon the study of the operative measures we must clear up certain questions, and first of these, the time of the operation. There are two opinions in regard to this: (1) Some defer intervention until after cicatrization is complete; or they even wait a more or less considerable time in order to give opportunity for latent foci of microbism to become extinguished so that the operation may be aseptic. (2) Others urge the necessity of early interference in order to prevent muscular atropy and ankylosis, and so do not hesitate to operate even when fistulas are present. Formerly I was a partisan of the first of the above mentioned opinions and I used to wait for one or two months after the closure of the fistulas; but I observed that, whatever delay there might be, one was never sure of having postoperative asepsis. so that in the case of the humerus I drained almost always and even left the focus open in the most infected cases. The good results that I thus obtained led me to operate even in fistulous cases. In the beginning I had some postoperative results which were somewhat disquieting and even the late results were mediocre. At that time I wrongly sought to close the wound by suture, but more re-

Fig. 4.—Case shown in Fig. 3, after treatment by an osteo-periosteal graft; consolidation in 36 days.

cently I drain very freely in these infected cases and have been struck with the good operative results and the firm consolidation obtained. Thus, although I believe that, as a general rule, it is preferable to operate in cases where cicatrization

has been complete for a certain time, I have become eclectic and in prolonged fistulous cases, when suppuration has become sluggish, instead of operating upon the fistula first and the pseudarthroses later, in certain cases I do not hesitate suture while

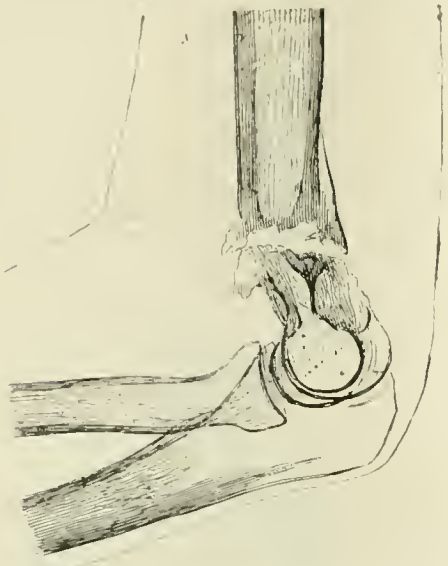

Fig. 5.—Juxta-articular pseudarthrosis.

suppuration is still present, and even when we do not get union we nevertheless gain some time, and we often obtain consolidation of the bone. I ought to say that decision in each particular case ought to be based upon experience. Thus in one case I contented myself in removing a sequestrum which kept the fistula open; and one month later, in examining the patient in order to determine when to operate on the pseudarthrosis, I found the spontaneous consolidation had occurred.

The second question is that of the advisability of the graft, I mean the complete, full sized graft having the purpose of restoring the humerus to its proper length. I know that cases have been published of successful grafting for pseudarthrosis of the humerus, but it is of so little importance to the arm to have even considerable shortening that I believe the bone graft is very rarely indicated. Several of my operative cases have very short arms (sometimes even more than 10 cm. shortening) and that without any functional trouble. Furthermore even in cases of successful grafting the arm always remains weak, and the possibility of fracture of the graft makes the prognosis doubtful. Finally I would add as a reason of the second order that if the radial nerve has been divided and muscular lesions are extensive, thanks to shortening of the skeleton of the arm, we shall be able more easily to suture the nerve and to repair the muscles. I myself in my 38 cases have never found any justification for grafting.

Operative Measures.—I have used various procednres in the treatment of pseudarthroses of the humerus. I shall not dwell upon the first stages of the operation, namely, incision on the external or posterior aspect of the arm, utilizing most often the cicatrix which is resected when it is adherent; denudation of the two extremities of the bone and freshening of the ends of the bone whether by the rongeur or the saw; examination of the fragments, after which one will decide upon the most appropriate osteosynthetic procedure. It is of these osteosynthetic measures that I wish to speak. I have employed the following procedures: (1) Plating; (2) silver suture; (3) clamp; (4) simple approximation without suture; (5) osteoperiosteal graft.

1. I have resorted most frequently to metallic plates, and I now use Lane plates or Sherman plates as being easier to apply to the irregular bone than are the Lambotte plates which I employed at first, and furthermore these latter are rigid while the first may be molded according to the necessities of the case. I have applied these plates in sixteen cases, three of which are still under treatment; of the thirteen others, eight are consolidated and five have either failed or are simply improved. I attribute this large number of unsuccesses to the fact that I tried to apply the plates to bones which were too friable, for in these cases the screws did not hold. The coaptation, notwithstanding one or two retention rings, was weak and the result was bad. At the present time I do not make use of plates except when the ends of the fractured bones appear to be sufficiently solid.

2. In other cases I rest content with a suture of silver wire. I avoid all complicated knots and apply simply a metallic loop perforating the fragments. I use silver wire because it is more malleable than the others—an important quality since we have to unite fragile pieces of bone. For the same reason I employ large wire (1^1_2 or 2 mm. in diameter) because there is less risk of its being broken. I leave the twisted ends rather long and draw them out through the drainage opening. In certain cases in which the line of fracture is wide and quite perpendicular to the axis of the limb, rigid coaptation is obtained. When the shape of the fragments lends itself to it when they terminate in sharp points, we may, by overlapping the ends of the fragments,

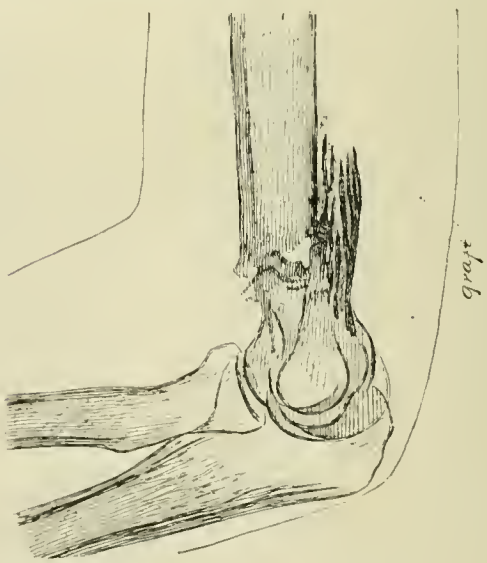

Fig. 6.—Osteoperiosteal graft in the case shown in Fig. 5; consolidation in 2 months.

previously shaped by the rongeur, obtain coaptation by means of two wire loops. This excellent method is easy of execution, can be rapidly done, and has given me several successful results. I have applied silver wire sutures in nine cases with

seven consolidations, one failure, and one case still in course of treatment.

3. I employed my clamps in two cases in which the formation of the bone rendered the use of the plate difficult, and in both of these cases consolidation was obtained.

4. In one case in which a fistula was present the multiplicity of foci and fungosities and the bad condition of the fragments forced me to bring together the extremities by making the points overlap without any retaining measures. The wound was left widely open. There was no reaction and the fragments were covered by fleshy granulations. The case is too recent, however, to know whether consolidation will be obtained or not.

5. Finally, in cases in which the fragments are in apposition and when there is only flexibility without a flail-like pseudarthrosis, I have had recourse to osteoperiosteal grafts after the method of Delagénière. I employ one or two grafts according to the case. Sometimes I have placed the graft above the metallic wire bringing the fragments in apposition. In ten cases of osteoperiosteal graft I have had eight consolidations and two failures. Of these ten cases, two only suppurated, and one of these, notwithstanding the complication, consolidated later. The second failure was in a case which had followed an aseptic course. I had placed an osteoperiosteal graft above the metallic wire approximating the fragments and a great improvement followed, but there is slight flexibility of the neck of the bone and the patient has absolutely refused a second operation.

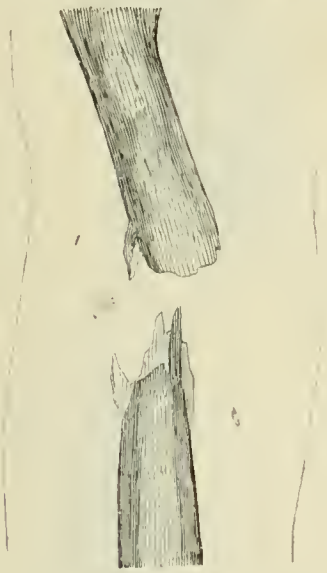

Fig. 7.—Fracture of the humerus with extensive loss of substance; treatment by screw plates. The radial nerve was divided by the bullet, was sutured, and regeneration occurred.

The great obstacle in the way of successful treatment of pseudarthroses of the humerus is suppuration. In my thirty-eight cases I had only twenty following an aseptic course. It is true that I operated in a certain number of cases that were still fistulous, in which union could not be attempted, and this frequency of suppuration (more than one-half the cases) is easily explained when one thinks of the condition of the bones that one is obliged to suture. In the course of operation on patients whose wounds were completely cicatrized, sometimes for several months past, I have found areas of fungous granulation and sequestra, some free, others buried in the medullary canal, and brought to light only when the saw had removed the extremity of the fragment. As a matter of fact, I

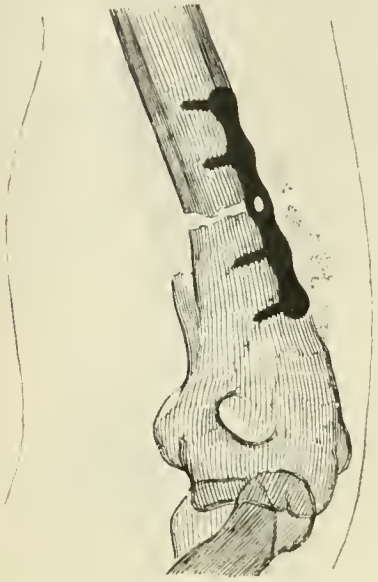

Fig. 8.—Same case as shown in Fig. 7, two months after operation.

drained most of my operative cases, either by having the twisted end of the metallic wire come out through the wound, or by establishing filiform drainage with a wisp of horse hair; or finally, in very bad cases, leaving the wound widely open, or simply placing a few horse hairs at the extremity of the incision.

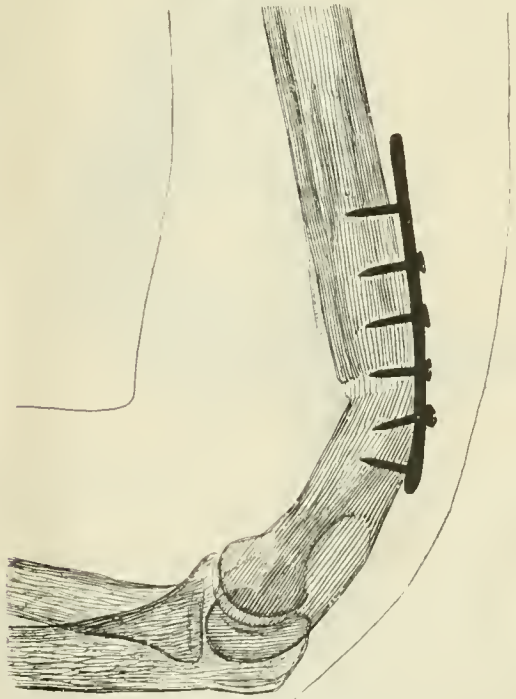

Fig. 9.—Same case as shown in Figs. 7 and 8, ten months after operation.

Sometimes, when the loss of bony substance is extensive, the muscles and skin bow out laterally after the bones have been sutured. I have on sev-

eral such occasions sutured the muscles and skin from above downward at the point of this lateral bulging. The suture was made in these cases in the form of a cross the center of which was left open to permit of drainage. After I began to use drainage my immediate results were better, and the later results also were much more favorable. The wound filled up very rapidly, and the consolidation of the bone was not in any way retarded.

Immobilization of the Limb.—In order to immobilize the limb after intervention, I first used the plaster bandage, or Delbet's apparatus, but of late I have almost abandoned this. I now employ a very large cotton dressing, immobilizing the arm parallel to the body and the forearm along the anterior surface of the thorax. One can apply it in such a way as to leave the wound exposed, thus

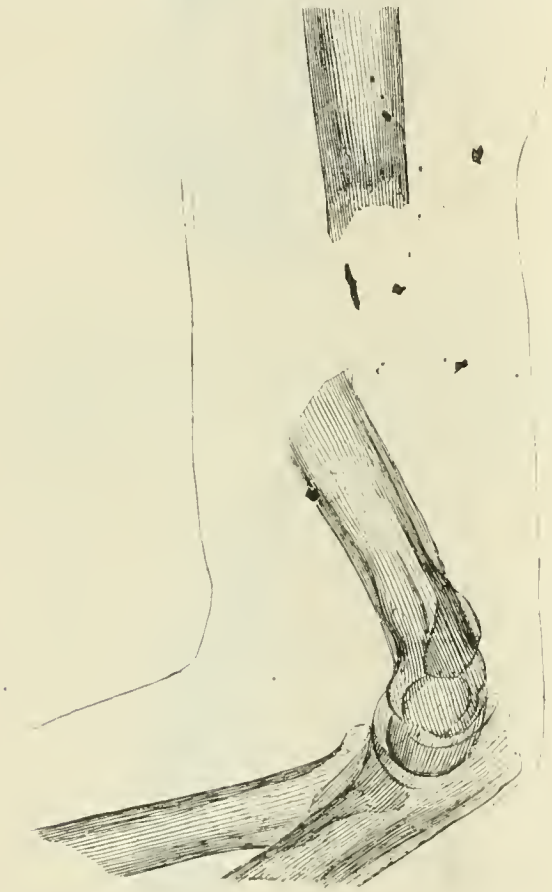

Fig. 10.—Fracture with extensive loss of bone.

permitting of dressing without affecting the immobilization of the member. This is a great advantage in all postoperative treatment.

Radial Nerve.—When the radial nerve has not been injured one must be very careful to avoid this nerve during the operation. It is not always easy, however, during the treatment of one of the extremities of the fragments, as the fibrous tissue covering the latter, and sometimes the radial nerve itself, cannot always be successfully dissected away. In order to avoid a lesion of the nerve we must proceed slowly and methodically. A special assistant watches the patient's hand during the operation, and if the surgeon gets too near the nerve, or stretches it, a quick movement of retraction is noted in the hand. One must then be cautious, and not cut widely into fibrous tissue or use the raspatory brutally.

In the course of my operations I have noted the following accidents: In one case the nerve must have been stretched, for although it was not perceived at the time, radial paralysis occurred later; this paralysis was not permanent, however, and the power of motion reappeared after some weeks. In a second case, while operating in a mass of sclerosed tissue, the nerve was caught in a loop

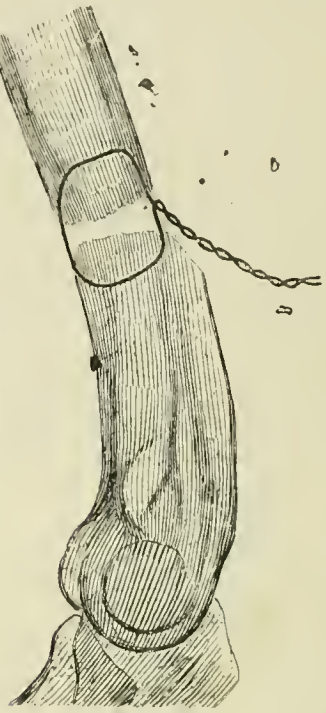

Fig. 11.—Same case as shown in Fig. 10, with silver wire suture in position.

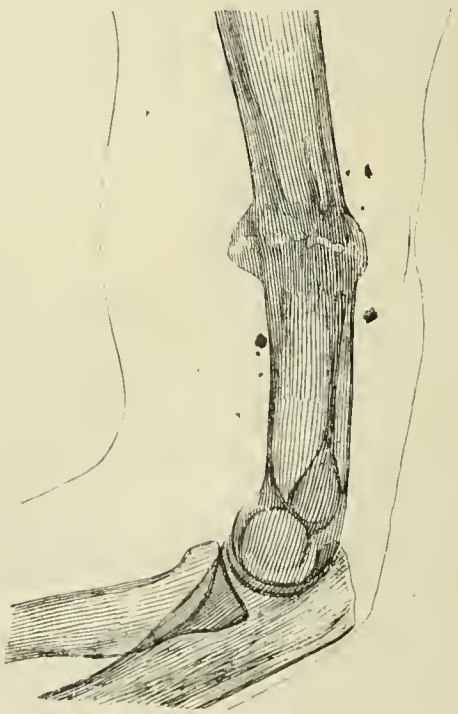

Fig. 12.—Same case as shown in Figs. 10 and 11, taken one year after operation, showing complete union.

of catgut. I discovered this a few minutes later, and at once divided the catgut, but complete radial paralysis resulted nevertheless. Regeneration was rapid, and at the end of a month the power of contraction reappeared in the long supinator, then extension of the hand became possible, and the movements of the thumb were the last to return. Finally, in another case, in getting at one of the fragments in a cicatricial mass, a quick movement of the hand showed that the radial nerve had been injured. The nerve was dissected out of the fibrous mass, and there was a notch in it involving about one-third of its fibers. An immediate suture was practised, and the first signs of motor regeneration appeared at the end of four months. The regeneration was finally complete.

FIG. 13.—Fracture of upper end of the humerus, with displacement of the upper fragment.

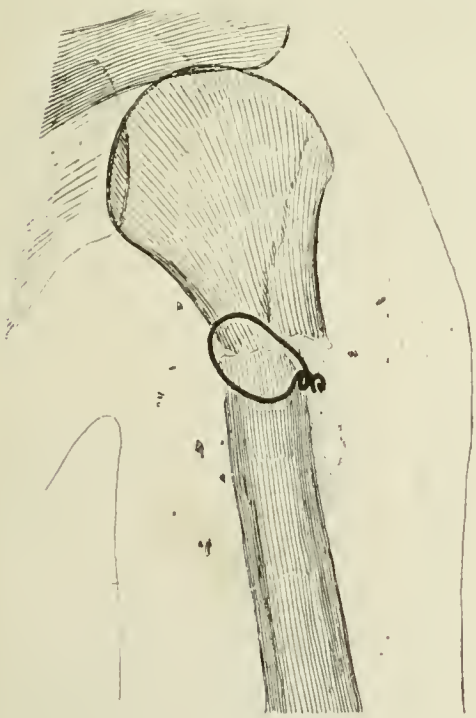

FIG. 14.—Same case as shown in Fig. 13, one month after operation.

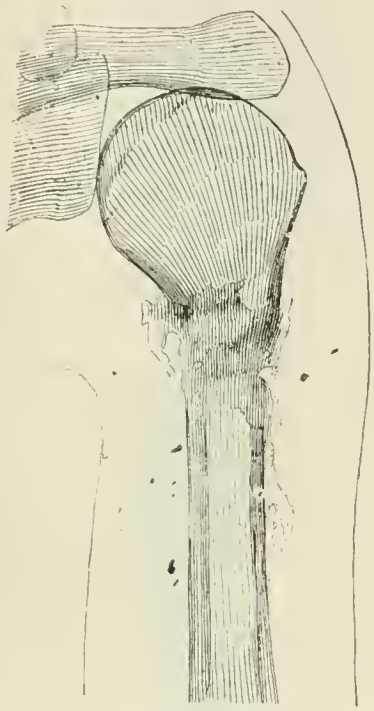

FIG. 15.—Same case as shown in Figs. 13 and 14, four months after operation.

FIG. 16.—Pseudarthrosis of the upper portion of the humerus.

When the nerve has been wounded before the operation I usually endeavor to find the two ends and to suture them. I have done this double operation in five cases. As the arm is shortened by the

freshening and bringing together of the fragments, suture can be made in a healthy part of the nerve without stretching it. One often has difficulty in burying the sutured nerve in healthy tissue. Sometimes, too, the nerve crosses the bone where there is a metallic plate, and that is a disadvantageous condition for regeneration. Furthermore,

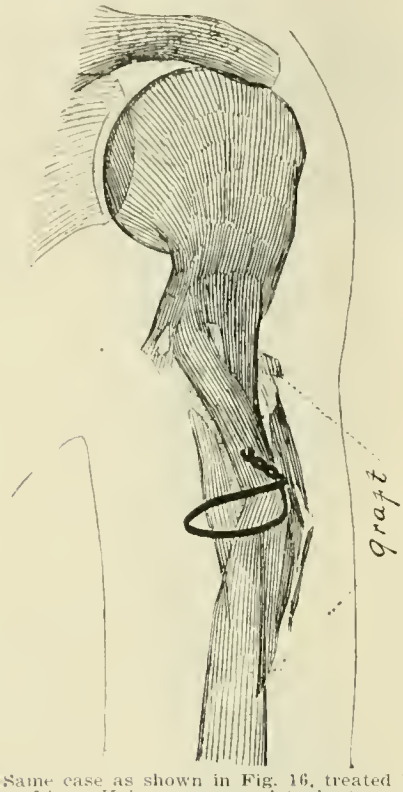

Fig. 17.—Same case as shown in Fig. 16, treated by cerclage and grafting. Union was complete in two months.

if it becomes necessary later to remove the plate, one runs the risk of wounding the nerve in the course of the operation. I have more than once encountered this difficulty. In one case the pseudarthrosis was consolidated and the nerve was completely regenerated, but there were two fistulous openings corresponding to the extremities of the plate. In order to avoid wounding the nerve I had to operate on the patient without an anesthetic, and I had the greatest difficulty in withdrawing the plate, which was enclosed in a complete canal of newly formed bone tissue. Therefore, whenever possible, I first suture the nerve, which I pass to the inner side of the bone and bury it in the biceps or anterior brachial, and then I proceed to the osteosynthesis of the humerus. Then the removal of the plate, if it becomes necessary, does not endanger the radial nerve. Of my five cases of double operation I had two in which I was able to obtain bony consolidation and regeneration of the nerve.

My results are shown in the following table:

Operation.	No. of Cases.	Consolidation.	Failure or Improvement Only.	Still Under Treatment.
Plate	16	8	5	3
Metallic suture	9	7	1	1
Clamp	2	2		
Osteoperosteal graft	10	8	2	
Screw	1			1
Total	38	25	8	5

Omitting the cases still under treatment, I have therefore obtained 25 consolidations in 33 cases; that is, 75.7 per cent. My statistics in regard to pseudarthrosis of the humerus give far less favorable results than some others. In the total number of other pseudarthroses the percentage of cures approaches 90. The time required for consolidation has been as follows: 1 month, 3 cases; 2 months, 12 cases; 3 months, 2 cases; 4 months, 3 cases; 5 months, 1 case; 7 months, 1 case; 10 months, 1 case; 11 months, 1 case; 1 year, 1 case; total, 25 cases.

Medicolegal Notes.

Traumatic Hernia.—In suit for compensation under the Wisconsin Compensation Act for personal injuries claimed to have been received in the course of employment resulting in hernia, the Industrial Commission found that the evidence did not justify a finding that the hernia was proximately caused by the alleged accident, and dismissed the application on the following grounds: "Inguinal hernia rarely results from accident. It comes from inherited or acquired weakness, and develops gradually. Because of this it has been necessary for the commission to require definite proof that the hernia was produced by accident. The applicant must prove that the accident was such as could produce a hernia, that the hernia appeared immediately after the accident, that it was followed by pain immediately disabling the applicant, and that the applicant gave immediate notice of the injury to the employer. The commission was satisfied, from a careful examination of the evidence, together with the written statement of admissions made by the applicant, that he had failed in his proof. If the applicant had sustained a hernia on the date of the accident he would have suffered pain, and would not have been able to continue his work for two weeks. The Wisconsin Supreme Court sustained this finding.—Meade v. Wisconsin Motor Mfg. Co. (Wis.), 169 N. W. 619.

Health Officers' Right to Fees.—The Iowa Supreme Court holds that a health officer, appointed by the local board of health under Iowa Code 1897, §2568, has no right by virtue of his appointment to administer to the sick of the township at the expense of the county, and when he renders services the requirements of Code Supp. 1913, §2571a, must be observed before the county is liable. That section makes a written order of the board of health a prerequisite to compensation, and such a health officer who administered to persons in the township afflicted with smallpox cannot recover from the county, where he did not act under a written order. The fact that the county board of supervisors rejected his claim without specifying the reason did not entitle him to recover against the county, for, had the reason been specified, the defect could not have been cured so as to render the county liable.—Lacy v. Monona County (Iowa), 169 N. W. 760.

Contributory Negligence in Malpractice.—It is held that a patient cannot recover for the improper treatment of a broken arm where the physician was prevented from making a proper diagnosis and from properly placing the broken bones by the refusal of the patient and her family to permit him to administer chloroform or to secure another physician to give him needed assistance. Such refusal constituted contributory negligence.—Summers v. Tarpley (Mo.), 208 S. W. 266.

Hypothetical Questions.—The rule prevailing in Alabama for propounding hypothetical questions is stated to be, in effect, as follows: Such questions need not hypothesize every fact in evidence, but may incorporate only sufficient facts in evidence to fairly justify the formulation of an opinion on the material issue on which the testimony is offered. The frame and substance of the question is a matter largely committed to the sound discretion of the trial court. Such a question is held objectionable if it contains elements of fact not shown by the evidence.—Miller v. Whittington, Alabama Supreme Court, 80 So. 499.

ALIMENTARY HYPERGLYCEMIA.

THE question of sugar tolerance has always been an interesting one to investigators and with the development of accurate methods for the estimation of the blood sugar the interest has increased. Glucose can be given readily by mouth, and the changes in the blood sugar followed at frequent intervals, with not a great deal of discomfort to the person being examined. An extensive study of the changes in the blood sugar following the ingestion of 100 grams of glucose on a fasting stomach was made by Hamman and Hirschman (*Archives Int. Med.*, 1917, xx, 761) on a number of patients suffering with various diseases. They made no attempt to construct any theory on the basis of the figures they obtained but limited themselves to a discussion of the findings. Briefly, they found that in normal persons there occurred only a moderate hyperglycemia which quickly subsided, while in diabetes, chronic nephritis, and deranged thyroid and hypophyseal function there was apt to be a much more pronounced and lasting hyperglycemia. They determined the renal threshold in normal persons as being between 0.17 and 0.18 per cent. of blood concentration, but pointed out the important fact that as the kidneys secrete sugar there is a tendency for the threshold to fall so that sugar may be found in the urine even after the blood sugar has dropped to 0.10 per cent.

At the same time, Denis, Aub, and Minot (*Archives Int. Med.*, 1917, xx, 964) and more recently McCaskey (*Jour. Am. Med. Assn.*, 1919, lxxiii, 243) observed that a marked hyperglycemia is a constant manifestation in hyperthyroidism and showed that this increased sugar content may persist in the blood for a relatively long time. The determination of the patient's reaction to the ingestion of 100 grams of glucose may therefore be of help in the diagnosis of this condition. It is emphasized that hyperglycemia is not present when the patient is fasting. These results are supported by the findings of Janney and Isaacson (*Archives of Int. Med.*, 1918, xxii, 160) who found that the removal of the thyroid in dogs resulted in a hypoglycemia.

Recently the reaction has been studied in cancer by Rohdenberg, Bernhard, and Krehbiel (*Jour. Am. Med. Assn.*, 1919, lxxii, 1528), who give figures which apparently show a characteristic blood sugar curve following the ingestion of 100 grams of glucose in patients suffering from malignant disease. In patients with cancer in any part of the body the percentage of blood sugar two hours after the ingestion of the glucose was as high as or higher than it was forty-five minutes after. These authors investigated twenty-four cases and found this response constantly. In any consideration of the worth of such a test as a means of diagnosis it must be remembered that disturbances in absorption would necessarily affect the shape of the blood sugar curve and such changes might be expected in any disease of the alimentary tract. But aside from this possibility one may find in the article by Hamman and Hirschman above noted protocols of a number of cases in which the blood sugar curve is of the type which is said to be diagnostic of cancer. These cases were of diabetes, chronic nephritis, hyperthyroidism, and dyspituitarism. Further, McCaskey found that thirty per cent. of his cases of hyperthyroidism had curves of this same character. Evidence is lacking to show whether all cases of cancer show this curve, though Hamman and Hirschman include one case which did not show it. It is of course freely admitted that the test cannot be condemned without a fair trial and that up to date no papers have appeared dealing with this particular question. But we have a fair amount of evidence in the literature above noted and one is forced to conclude that Rohdenberg, Bernhard, and Krehbiel's cancer test will probably not find supporters in the future.

LEONARDO DA VINCI.

IT should be a matter of rejoicing to all medical men to read what Havelock Ellis has to say on the subject of Leonardo Da Vinci in a recent number of *The Nation* (London), for it is a cleanly representation of the painter's life and aims and fruitions, and moreover is so appreciative of the lights and so disdainful of the weight of the obscurities in the man's character that, even though we know Ellis to be a disciple of Freud, his utterances, in the Freudian manner, are of so weak a nature that we doubt very much if Freud will continue to recognize him as his most enthusiastic English disciple, barring Ernest Jones.

After Freud had given to a more or less grateful world his book "Leonardo Da Vinci: A Psychosexual Study of an Infantile Reminiscence," every medical man who was held in the thrall of the Freudian theories and whose reasoning powers were not of the strength to withstand their allurements, became so confirmed in his partisanship and so intolerant of criticism that for a time the name of Da Vinci was taboo and the few champions of the purity of his life and the vindication of his character offered a slight obstacle to the engulfing onrush of adverse criticism. Excuses were made by the champions—half-hearted ones, lest they themselves would be classed as "those rebel spirits

adjudged to hell"; and naturally they came in for a sound thrashing for having the temerity and the weakness to offer an excuse. Hence, the opposition to the Freudian interpretation was as naught; and after a few ineffectual struggles most of the medical world passed into that state of acceptance that makes for content, albeit content is always host sooner or later to apathy.

But the Great War has wrought good out of evil; it has clarified men's thoughts. The apathetic state of acceptance of a theory, just because it emanates from a student of a special form of science, is no longer considered an enviable state; in fact, the man today who has the hardihood to stand up for the easy-going mental attitudes of prewar times finds himself isolated and the target of censorious remarks on the part of his intelligent fellow men. This may be going to the other extreme, but in the case of Freud and his followers and also in the case of other medical visionaries, who will deny that this desire to blot out the old way of allowing theorists to obsess our mental faculties without demur will not result in a sharpening of our wits, in a critical faculty that will easily differentiate between what is pinchbeck and what is gold?

In a recent book, Albert Mordell's "The Erotic Motive in Literature," we again see the harmful results of a writer being an out-and-out Freudian and his blinding to that fundamental need of life—common sense. Imagine anyone, in full possession of his mental faculties, detecting the erotic experiences during babyhood in Browning's "How We Brought the Good News from Ghent to Aix" or "The Last Ride Together," or in Wordsworth's "Up with Me into the Clouds"? And yet these and other instances in poetry are stated in all seriousness as unmistakable evidences of the authors being swayed by the "unconscious." Why not take also those acid-etched lines by Blake: "Mock on, mock on, Voltaire, Rousseau," and prove along Freudian lines that Blake's hatred of the atheism of the two Frenchmen shows conclusively the fact that the English mystic selected two rather wicked Frenchmen because of erotic experiences in his youth, which resulted from his hearing, on more than one occasion, voices, distinctly male, and which occurrence shows his early tendencies toward sexual inversion!

But why concern ourselves with Mordell and others, when medicine, modern medicine, has achieved the great triumph of winning back to sanity so clear a thinker and so gifted a medical man as Havelock Ellis? His essay on Leonardo Da Vinci has the touch of maturity as regards the point of view; the maturity that has shaken off the incrustations of the falsities of the teachings of others, no matter how deep the impress was and no matter how far the swerving in the past. It is a declaration to the public that at last a typical Freudian has renounced his "religion" and has come out into the clear sunshine where persons and objects may be judged for what they are really worth.

THE PATHOGENESIS OF INFLUENZAL ARTERITIS.

Bacteriological examinations are as yet too insufficient to give any data relative to influenzal arteritis, and in the only case where one was made the streptococcus was found. Therefore, in this instance the agent was one of a secondary infection. On the other hand, if the cases of arteritis occurring in other infectious diseases are considered, what do we find? The bacteria of typhoid fever, pneumonia, and erysipelas occasionally give rise to arteritis, and out of eight typhoid cases Rattone found the specific bacillus seven times in the walls of the arterioles of the myocardium and in their vasa vasorum. But in about all the cases in which the arteries of the limbs have been involved the process has been due to a secondary infection. It has, however, long been known that the organism of influenza is, perhaps, the most apt to open the door to secondary infections, and as far back as 1890 Gerhardt, from a long experience, said that "it seems that the complications and affections following influenza are legion and in this respect the most uncommon lesions are met with."

Now, although we know the astonishing aptitude of bacteria for modifying their virulence under well determined conditions, it would be difficult to attribute to Pfeiffer's bacillus alone (assuming this to be the influenza bacillus) all the affections which have been observed to follow in the wake of influenza, and recent experience has amply demonstrated the rôle of the streptococcus, staphylococcus, and pneumococcus in meningeal, pulmonary, and pleural inflammatory processes following grippe. It is during convalescence—the period *par excellence* of secondary infections—that arteritis occurs, and in all the reported cases with which we are familiar, the influenza was either exceptionally severe or the patient imprudently shortened his convalescence—conditions eminently suited for the development of secondary infections. For the time being, at least, it would seem logical to assume that the agents of secondary infection play an important part in the pathogenesis of influenzal arteritis, although it must be admitted that the last word has not been said on the subject.

The study of the toxins of the influenza bacillus has hardly been commenced. This means that it would be difficult to admit or reject a purely toxic arteritis solely due to the products secreted by the assumed pathogenic agent of influenza. But on the other hand, experimental arteritides have been produced by intravascular injections of the toxins of the streptococcus, staphylococcus, etc., and long since Claude found an endoperiarteritis in the liver and kidneys following experimental intoxications which he produced with the toxins of the organisms of diphtheria, tetanus, and other infections. The only conclusion that can be deduced from these data is that the agents of secondary infections produce in some cases lesions of the intima solely by their toxins.

CYSTS OF THE IRIS.

THE symptoms of a cyst of the iris usually appear quite a long time after the receipt of the trauma, the usual causal factor of this ocular lesion. First of all a tumor is noted, and its growth is in direct relation to the symptoms of irritation, made evident by mild inflammatory attacks. The eye frequently adapts itself quite well to the cyst, but occasionally, when the tumor continues to grow, there may be a certain amount of intolerance. By its invasion of the pupillary field it interferes with the sight, while occasionally periorbital pain, photophobia, and lacrymation arise. The complications which may ensue from a cyst of the iris are glaucoma, which results in more instances from the compression exercised by the tumor on the sinus venosus sclerae, iridochoroiditis, and sympathetic ophthalmia.

The diagnosis of cysts of the iris is easy. The cyst offers itself as a small, smooth, rounded tumor, occasionally bilobate or multilobate. When transparent the cyst is of the serous variety, while the pearly cysts are, on the contrary, of a brilliant nacreous white. In the majority of cases the etiology, the evolution, and the evident benignity of the process distinguish these cysts from sarcomata of the iris which have a rapid evolution. Gummata of the iris are generally more yellow in hue and both eyes are apt to be involved, but where doubt exists antisyphilitic treatment will settle the diagnosis. Tubercles of the iris coincide with pulmonary lesions or evidences of tuberculosis in other viscera. Their evolution is rapid, they suppurate early, and are the cause of an hypopyon or ulcerating keratitis.

From their very nature, cysts of the iris are benign growths and usually serous cysts do not increase in size. When extirpation has been incomplete or if the cyst has only been punctured, a recurrence takes place. From the effect of any kind of irritation pearly cysts are apt to increase in size which may interfere with the sight or even be the causal factor of glaucoma. They are endowed with a low vitality because they are composed of epidermic cells, similar to the horny stratum of the epidermis, but they have no tendency to ulcerate and are usually painless. When extirpated completely and in due time, they do not recur. Before removal, all inflammatory phenomena should be guarded against because, although the eye tolerates these cysts, an ophthalmia, with all its disastrous consequences, may be excited by the operation.

BACTERIOLOGY OF GRIPPE PNEUMONIA.

DESPITE the enormous literature of this subject, it is always of interest to obtain conclusions from sources somewhat remote from our own. In the *Nederlandsch Tijdschrift voor Geneeskunde* for April 26 two bacteriologists of the Hygienic Institute of Amsterdam record their methods of work and deductions therefrom. Whatever the cause of the pandemic, there can be no doubt that the high mortality was due to the great number and variety of secondary infections. It was found that when the well-known "heliotrope cyanosis" set in, accompanied by a rise in the pulse, the blood swarmed with microorganisms and death was probable within a short time. It was at this juncture that cultures were taken. In three cases the pneumococcus was cultivated and in three others the hemolytic streptococcus. The same organisms were found in pleural exudates, while in the sputum the first in frequency was an anhemolytic streptococcus, the hemolytic form as well as the pneumococcus being conspicuous for their rarity. Thus of 16 cases no less than 12 were characterized by the anhemolytic form. To return to the subject of blood cultures, a majority of the latter were sterile, but nine in 21 giving positive results. As implied above, only six were available for study. The pathogenicity of the pneumococcus and streptococcus as discovered in other countries holds good for Holland. It is well known that in given localities now one and now the other predominates. The authors do not even mention Pfeiffer's bacillus, although if present one expects to see it in the terminal bacteriemia. Neither do they have any explanation to offer for the negative blood cultures, whether due to sterile blood or technical errors.

News of the Week.

Red Cross Announces Fall Campaign.—Dr. Livingstone Farrand, Chairman of the Executive Committee of the American Red Cross, announces plans for a nationwide Red Cross campaign opening Monday, November 3, and closing Armistice Day, November 11. The campaign will be known as the Third Red Cross Roll Call and will have for its primary object the enrollment of members for 1920. There will be in addition a general appeal for $15,000,000 to enable the organization to complete its war obligation at home and abroad. The Red Cross programs are primarily within the field of public health and will aim particularly at cooperation with official activities, Federal, State, and local. An effort will be made to avoid duplicating the work of established organizations and the endeavor will be to supplement other agencies where they already exist or to stimulate or organize work where none exists. The home program includes preparedness for disaster relief, a widespread nursing plan, first aid instruction, and a Junior Red Cross program.

Harvard Adopts New Physical Training System.—Harvard University will adopt this year a program of compulsory athletics or physical training in an endeavor to answer the question as to why 40 per cent. of the young men of America were turned down after examination by the draft board physicians as physically unfit for military service. The fundamental basis of the new plan is expressed by the slogan "Get everybody into the game." The idea is to make physical exercise attractive, and to show the student what a tremendous benefit it is to him to have a well kept body and a well trained body as well as a well kept and well trained mind so that every boy in high school or college will be keen for physical training. Dr. Dudley J. Sargent, director of the Harvard

gymnasium, several years ago declared that the team idea in college athletics is fundamentally wrong and that the systems of physical instruction will have to be changed if the youth of America are to get the benefit from them that they should get. In connection with the new system of physical training, there is to be a certain amount of lecture instruction, which will aim to give the theory of why physical training is desirable, and the simple things of ordinary hygiene of all sorts. The question of sex hygiene is to be met, not as a special feature, but in its relation to other things. For this part of the work the Social Hygiene Board has made a grant of $13,000 for personal services in connection with the university's physical training experiment. The authorities of Harvard feel that if they are able to develop their plan to full fruition other institutions will adopt it and it may be brought about that the next generation of young men will not be 40 per cent. unfit for military service. Dr. Roger Lee, the university's professor of hygiene, is largely responsible for the development of this plan.

A New Health Department Building for New York City.—The erection of a new Health Department building in New York City has been made possible by an appropriation of $1,000,000 granted by the Board of Estimate. The new structure will be located on a plot of ground, 100 x 100 feet, in West Thirtieth Street, between Seventh and Eighth Avenues. The new building will provide space for the offices of the Director of the Bureau of Hospitals and the Director of the Bureau of Laboratories which are now located at a distance from the central offices. In the new building three or four floors will be given over to the laboratories. The first floor will be for the Bureau of Records and another floor will be a modern health station where clinical work will be done. A floor will also be devoted to a medical library.

Sea View Hospital Transferred to Health Department.—The Health Department has taken formal possession of the Sea View Hospital, Staten Island, for use as a home for the victims of drug addiction. The Committee on the Prevention of Tuberculosis has written to the Mayor, the Health Commissioner, the Charities Commissioner, and the members of the Board of Estimate, protesting against this action. The Staten Island Civic League declares that it will take drastic steps to prevent the use of Sea View by drug addicts.

Italian Babies Perishing for Lack of Milk.—In a recent appeal made by the American Free Milk and Relief for Italy for $100,000 with which to buy dry milk and condensed milk for babies in Italy, the statement is made that the relief agencies have been feeding only 30,000 to 35,000 babies in Italy, which is about one-tenth the number that should be fed. During the war 93 per cent. of the cattle were killed for the purpose of feeding the families of Italian soldiers. During the epidemic of influenza over 1,000,000 persons died in Italy, thus leaving many nursing babies behind. Thousands of these babies have died from lack of nourishment It is said that unless quantities of milk are sent to Italy during the next year there will be few babies left alive.

Smallpox Among Crew of Fishing Vessel.—A man with smallpox walked into one of the Venereal Clinics of the New York Department of Health recently. It was found that he was a member of the crew of a fishing vessel that had discharged a cargo at Promised Land, L. I., and subsequently came into the Port of New York to coal. It was also learned that another member of the crew was detained in Jersey City suffering with what was designated chickenpox, and, in addition, two other members were sick at Promised Land. Investigation by a committee of physicians revealed that the men were all suffering with smallpox. Since then eight additional cases have developed among the crew of the original vessel and a sister ship. The United States Public Health Service has been advised of the facts with a view to having action taken that will bring to light the true situation in Nova Scotia, where it is reported that smallpox is widespread.

Drug Addiction Made Reportable.—At a meeting of the Board of Health of New York City on July 22, 1919, the following resolution was adopted: "Resolved, that Section 1 of the Sanitary Code be and the same is hereby amended by adding thereto a new subdivision, to be known as Subdivision 47, to read as follows: 'Pestilential Disease: Shall be deemed to include the conditions and symptoms resulting from the habitual use of habit-forming drugs, and known as drug addiction.'"

Sued for Typhoid Outbreak.—Seven suits for damages aggregating $125,000, have been brought against Francis P. Garvin and his wife, Mrs. Mabel Garvin of New York, by residents of Saranac Lake, Tupper Lake, Malone, and Plattsburgh, charging that they were responsible for an outbreak of typhoid fever among the men employed in the construction of Kamp Kill Kare on Racquette Lake early in the summer of 1916. The men became ill while engaged in the reconstruction of the old Timothy L. Woodruff camp at Arietta, between April 1, 1916, and July 5 of the same year. There were 129 men employed and a number of them died during the typhoid epidemic.

Sir Shirley Murphy, formerly Health Officer of London, is now in this country as an official delegate of the British Government, studying advanced methods of medical progress, with particular reference to preventive medicine and public health.

Dr. Emil Goetsch, associate professor of surgery in Johns Hopkins University and surgeon to Johns Hopkins Hospital, has been appointed professor of surgery and visiting surgeon to the Long Island College Hospital. He will be director of the surgical service and head of the department of surgery throughout the college, hospital, and dispensary.

Dr. Alonzo E. Taylor of Philadelphia, Chief of Surveys of the American Relief Administration, has returned from a tour of the war-torn countries of Europe.

Promotions in the Reserve Medical Corps of the U. S. Navy.—The following members of the Reserve Medical Corps of the Navy, in addition to those whose names were published last week, have been promoted to the rank of Commander: Drs. Langhorne, Crow, Jacoby, Miller, Vaughan, Hille,

MacEvitt, Leland, Hines, Lee, Collins, Costello, Kimball, Henderson, Jones, Patton, Herriman, and Eldridge.

Ex-Army Surgeons Seek Employment.—The Reemployment Bureau for Soldiers, Sailors, and Marines states that recently as many as twenty-five physicians have registered with the agency. These physicians have returned to their former localities to find their practices gone and would like positions with industrial plants, in health departments, as ship's surgeons, etc.

Texas Doctors Increase Fees.—Physicians of Denton County, Texas, on August 6, voted a general increase in fees for professional services. Day calls are now $3 and night calls $4. Trips to the country are to be made for $3 with 50 cents per mile for mileage. Other rates were raised proportionately.

Drug Sellers Granted a Stay.—Dr. Solomon Rothman and Louis and William Cohen, druggists, recently convicted on a charge of violating the Harrison law by selling habit-forming drugs, were sentenced by the Federal Court to two years each in the Atlanta Penitentiary. A stay was granted and the defendants released on bail pending an appeal.

The American Public Health Association will hold its next annual meeting at New Orleans, Louisiana, October 27-30, inclusive. The central theme of discussion will be Southern health problems, including malaria, typhoid fever, hookworm, soil pollution. The program of the meeting will be published in the *American Journal of Public Health*, appearing October 5, or may at that time be had upon application to the Secretary, 169 Massachusetts Avenue, Boston, Mass.

Medical Society Elections.—The ALUMNI ASSOCIATION OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO has elected the following officers for the ensuing year: *President*, Dr. John A. Stapleton, Rochester; *First Vice-President*, Dr. Charles B. Kibler, Corry, Pa.; *Second Vice-President*, Dr. William C. Heussy, Seattle, Wash.; *Third Vice-President*, Dr. James H. Carr, Buffalo, N. Y.; *Fourth Vice-President*, Dr. Mary O'Malley, Washington, D. C.; *Fifth Vice-President*, Dr. John C. Lappeus, Binghamton, N. Y.; *Secretary*, Dr. A. H Aaron, Buffalo, N. Y.; *Treasurer*, Dr. Harry N. Feltes, Buffalo; *Chorister*, Dr. Norman L. Burnham, Buffalo; *Chairman of Executive Committee*, Dr. Harry E. Trick, Buffalo.

THE AMERICAN GYNECOLOGICAL SOCIETY, at its annual meeting, held in Atlantic City, June 16, 17, and 18, elected the following officers for the ensuing year: *President*, Dr. Robert L. Dickinson, Brooklyn, N. Y.; *First Vice-President*, Dr. J. Clarence Webster, Chicago; *Second Vice-President*, Dr. Jennings C. Litzenberg, Minneapolis; *Secretary*, Dr. George Gray Ward, New York; *Treasurer*, Dr. Brooke M. Anspach, Philadelphia.

THE FRANKLIN COUNTY (ME.) MEDICAL SOCIETY, at its annual meeting, held in St. Albans, June 18, elected the following officers for the ensuing year: *President*, Dr. Arthur O. Morton, St. Albans; *Vice-President*, Dr. C. S. Schofield, Richford; *Secretary*, Dr. E. A. Hyatt, St. Albans.

THE ASSOCIATION OF AMERICAN PHYSICIANS, at its annual meeting, held in Atlantic City, June 16-18, elected the following officers: *President*, Dr. Hermann M. Biggs of New York; *Vice-President*, Dr. William S. Thayer of Baltimore; *Secretary*, Dr. Thomas McCrae of Philadelphia; *Treasurer*, Dr. Joseph A. Capps of Chicago; *Recorder*, Dr. T. R. Boggs of Baltimore; *Councillor*, Dr. Lewis A. Conner of New York.

THE MASSACHUSETTS MEDICAL SOCIETY, at its 138th annual meeting, held in Boston, June 4, 1919, elected the following officers for the ensuing year: *President*, Dr. Alfred Worcester, Waltham; *Vice-President*, Dr. Arthur R. Crandall, Taunton; *Secretary*, Dr. Walter L. Burrage, Jamaica Plains; *Treasurer*, Dr. Arthur K. Stone, Framingham Center; *Librarian*, Dr. Edwin H. Brigham, Brookline.

THE TENNESSEE MEDICAL AND SURGICAL ASSOCIATION, at its annual meeting in Deyrsburg, May 29, 1919, elected the following officers for the ensuing year: *President*, Dr. D. J. Brewer, Newbern; *Vice-President*, Dr. H. W. Palls, Union City; *Secretary-Treasurer*, Dr. I. A. McSwain.

THE NORTH TEXAS MEDICAL ASSOCIATION, at its semi-annual meeting, held at Fort Worth, June 4, 1919, elected the following officers for the next term: *President*, Dr. H. Leslie Moore, Fort Worth (re-elected); *Vice-President*, Dr. Sidney J. Wilson, Fort Worth; *Secretary*, Dr. David L. Bettison, Dallas; *Treasurer*, Dr. M. L. Wilbanks, Fort Worth.

THE RHODE ISLAND MEDICO-LEGAL SOCIETY, at its meeting at Slocum's on the Pawtucket, June 26, 1919, elected the following officers for the ensuing year: *President*, Dr. Hanry A. Jones Howard; *Vice-President*, Henry J. C. DuBois; *Secretary-Treasurer*, Dr. Harry S. Flynn of Providence.

THE KENTUCKY VALLEY MEDICAL ASSOCIATION, at its annual meeting, held at Torrent, July 11, 1919, elected the following officers for the ensuing year: *President*, Dr. George F. Hoyle, Winchester; *Vice-President*, Dr. C. B. Marks, Lexington; *Secretary*, Dr. Wilgus Bach, Jackson.

THE RUTLAND (VT.) COUNTY MEDICAL SOCIETY, at its recent annual meeting in Burlington, elected the following officers for the ensuing year: *President*, Dr. J. W. Estabrook, Brandon; *Vice-President*, Dr. H. R. Ryan, Rutland; *Secretary and Treasurer*, Dr. C. H. Swift, Rutland.

THE TWELFTH DISTRICT MEDICAL SOCIETY OF THE STATE OF GEORGIA, at its meeting at Eastman, July 11, 1919, elected the following officers for the ensuing year: *President*, Dr. J. C. Wall, Eastman; *First Vice-President*, Dr. J. E. New, Dexter; *Second Vice-President*, Dr. Alfred Coleman; *Secretary and Treasurer*, Dr. J. H. Moore, Dublin.

THE MONTANA MEDICAL ASSOCIATION, at its annual meeting, held at Missoula, July 11, 1919, elected the following officers for the ensuing year: *President*, Dr. E. M. Larsen, Great Falls; *First Vice-President*, Dr. Lawrence Stevens, Laurel; *Second Vice-President*, Dr. P. H. McCarthy, Butte; *Third Vice-President*, Dr. A. W. Deal, Lewistown; *Secretary-Treasurer*, Dr. E. G. Balsam, Billings.

Obituary Notes.—Dr. HENRI M. AUGER, a graduate of the Buffalo Medical College, in 1886, and one of the founders of St. Mary's Hospital, Jamaica, L. I., died at his home there, on August 10, aged 62 years.

Dr. Herman E. Street, Brooklyn, died suddenly at the Peck Memorial Hospital on Monday of this week at the age of 73. He was graduated from the New York Homeopathic College in 1892 and served as intern at Bellevue and Flower Hospitals.

Correspondence.

THE INFLUENZA SCARE.

To the Editor of the Medical Record:

Sir:—It has been recently published through our metropolitan papers that medical authorities predict two more years of epidemic influenza in succession, and that these will be as bad or even worse than the first. Therefore, the writer of this article takes the liberty to protest against all this ill-omened prophecy and prognostication, and in the language of Stevenson, "renounce when that shall be necessary and not to be embittered", with a view of allaying a general apprehension and fear that otherwise seems likely to prevail. That some cases of influenza will appear in various parts of the country will not be a matter of surprise to us, but that it will become so widespread and fatal as last year is in no manner reflected in any of the signs noted by our observations, the opinions of advertised medical experts to the contrary notwithstanding.

The epidemic of 1918 was of the nature of a plague, spreading the germs of infection everywhere, and augmented by the depressing influence of the World War, together with abnormal food conditions. Now that the war is ended, and the former customs of living resumed with wholesome and adequate food, there remains but slight if any apparent reason for a repetition of another similar outbreak this coming season. Of course it is essential to comply with hygienic laws, and as far as possible look out for the safety of life and limb, but it is not wise nor consistent with the rules of prevention to advertise a calamity of which there is no likelihood, much less any positive proof that it will come to pass, and thereby cast a deadly gloom over the people. Such agitation serves only to bring about the very trouble which is to be avoided. This statement is substantiated by the known fact that a large number of the many deaths which resulted from the previous epidemic were evidently caused by fright, over exertion, nervous strain, and resulting debility.

That a weakened condition and a consequent lowered resistance paves the way for influenza, or any other general disease, was shown by an article in the *N. Y. Medical Journal* of Feb. 8, 1919, and recently quoted in the *Metabolist* as follows: "An observant hospital corps man of the Navy became so thoroughly convinced that lowered resistance was always the determining factor in contracting influenza that he and some of his mates volunteered to test the truth of his theory. The offer was accepted and 100 enlisted men who volunteered were submitted to exhaustive experiments by naval surgeons, the outcome of which seems to confirm the theory. These men were all in the best of physical condition, and during the experiment their health was looked after carefully. Live cultures of influenza bacilli were sprayed in their throats and noses hourly. The germs were introduced into their food. They were kept in close contact with patients suffering with the disease, and in order to obviate any possible individual immunity to one particular strain, the contacts were alternated frequently. Some members of the group received various preventive inoculations, but others were not thus protected. Not a single case of influenza was developed."

That medical scientists should be encouraged to find out the etiology of disease and specific cures for the same is perfectly legitimate and proper. For it is greatly due to their wisdom and skill that much lasting good has been accomplished within the past two decades. As to laboratories and equipment for research work, the very latest and best are already amply provided in our leading medical colleges and other scientific institutions. So that there is but a meager excuse, and in our judgment none, for asking the Congress of the United States to appropriate $1,500,000, to provide equipment simply to experiment and combat a possible or imaginary epidemic. And it should be vehemently emphasized that just such enormous appropriations and exorbitant taxes are already contributing factors in helping to bring about business embarrassment and economic stagnation, as well as a woeful state of depression and discouragement in this great nation. So if there is to be another epidemic, it will be brought about by rendering the inhabitants less able to withstand the ravages of disease because of the heavy burdens they are called upon to bear and the inordinate cost of living imposed upon them.

Let us suggest that these would-be benefactors, who are looking for a chance to benefit humanity, turn their attention to the epidemic of narcotic neurasthenia, which is now becoming more and more prevalent throughout the land, by reason of inefficient training and a lack of intelligent, sympathetic, and humane treatment.

J. C. Bateson, M.D.

Scranton, Pa.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, July 25, 1919.

Memorial to Hugh Owen Thomas.—Thomas of Liverpool, was one of the geniuses of orthopedic surgery and the war has effectively demonstrated the value of the appliances devised by him. Hugh Owen Thomas, who was born in 1834, was a student of medicine at Edinburgh at the same time as Goodsir, Syme, Spence and Simpson, when Turner, the late professor of anatomy and principal of Edinburgh University, was demonstrator of anatomy. He also studied at University College, London. After he had qualified he took up practice in Liverpool interesting himself almost wholly with orthopedic surgery and practising chiefly in connection with workmen's societies and at the docks. Thomas possessed really remarkable mechanical aptitude, devising and superintending the construction of his own splints. He became an expert metal worker and in many branches of orthopedic surgery was a pioneer. In 1876 or thereabouts he published a work on the treatment of disease of the hip, knee, and ankle joints. It is a tribute to his surgical knowledge and ingenuity that his inventions and devices

have stood so well the test of time, that in principle they have been but little improved upon, and have proved an immeasurable boon to many of the sufferers of the war just past. The Medical Institution of Liverpool has organized a scheme by which his memory may he kept green and it may be anticipated that the response will be generous. It may be mentioned that Thomas was the uncle of Sir Robert Jones of Liverpool, the well known English orthopedic surgeon.

The Ophthalmological Congress at Oxford.—The tenth annual meeting of the Oxford Ophthalmological Congress took place on July 10 and 11 last. The scientific proceedings were held in the department of human anatomy of Oxford University and the meeting was opened by the Master of Keble College, Mr. Sydney Stephenson. Among the papers read was one on the ocular complications of dysentery by Major Walter H. Kiep, R.A.M.C., which was followed by an excellent discussion. Major Edgar H. Smith, R.A.M.C., read a paper concerned with Quinine Amaurosis which was also fully discussed. Dr. William McLean of New York, contributed a paper in which he described the further experimental studies in intraocular pressure and tonometry and showed his latest model tonometer. In the afternoon of the tenth members and their friends were entertained at tea in the gardens of Trinity College. In the evening the anual dinner of the Congress was held in the hall of Keble College at which some 70 members and visitors were present. On July 11 Dr. Lewis Ziegler of Philadelphia, opened the proceedings by reading a paper on the problem of the artificial pupil; knife-needle versus scissors. Next Dr. P. Baillart of Paris described his dynamometer for determining the blood pressure in the branches of the central retinal artery. Mr. A. F. MacCallan of Cairo read a paper on the seasonal variations of acute conjunctivitis in Egypt. Colonel A. H. Tubby suggested investigation with regard to any possible connection between skeletal asymmetry, on the one hand, and defects of the eye on the other.

Three blind speakers discussed the question of the employment of the blind. These were Mr. Adolphus Duncombe, Captain Pierson Webber and Captain Towse, V.C. During the afternoon the Ashurst War Hospital at Littlemore, near Oxford, was thrown open to members by Lieut.-Colonel T. S. Good, R.A.M.C.

Organization of the Medical Staff of the Ministry of Health.—Now that the establishment of a Ministry of Health has become an accomplished fact the matter of the organization of the medical staff has been settled. The medical staffs of the Local Government Board and of the National Health Insurance Committee are to form the main part of the medical staff of the Ministry. However, the entire system has been reorganized, and several additional parts created. Sir George Newman, K.C.B., has been appointed Chief Medical Officer of the Ministry, his status being that of a Secretary of the Ministry. Sir George Newman is also allowed by special arrangement to retain his position as Chief Medical Officer of the Board of Education. Five new posts of "Senior Medical Officer" have been established, with status corresponding to that of Assistant Secretary. One of these is Dr. Janet M. Campbell, who will also by arrangement with the President of the Board of Education act as Chief Woman Medical Adviser of that Board. The remainder of the established medical staff of the Ministry will be in one grade and will be known as "medical officers." These will comprise those of the existing medical staffs of the Local Government Board and of the Insurance Commission who have not been appointed already, with the addition of new officers yet to be appointed as may be required. Besides the regular staff, arrangements have been made by which the Ministry may secure the services from time to time of specialists and others, on a part-time basis.

The Health Councils under the Ministry of Health.—The proceedings of the Ministry of Health, it was provided in the Act, are to be assisted throughout by various advisory councils, and medical men have always felt that the institution of strong advisory councils formed one of the greatest assurances that the Ministry would be placed in actual touch with the things that happen, and in actual possession of the knowledge required for betterment and development. The draft orders establishing these Consultative Councils for England and Wales have now been issued, and although their personnel has not yet been published, it is stated that they will be composed of persons of practical experience. There are to be five such councils, four for England and one for Wales. The four for England will each consist of twenty persons, men and women, and each council will have special duties as follows: (1) For medical and allied service; (2) for local administration; (3) for national insurance; (4) general. The council for Wales is a mixed body of thirty persons, men and women, covering between them all the four subdivisions represented by the four English councils. The number of councils being limited to five, and none of them being very unwieldy in size, the chances that the Minister of Health will get prompt advice along any line where he seeks it seem good. The *Times* startled the medical world last week by stating that there would be fifty councils, the blunder being caused by adding the twenty persons of each English council to the thirty of the Welsh council, and then thinking that each person was a council!

The usual method will be adopted to secure that there is a due introduction of fresh blood upon the councils. The members are elected for three years, but during the first three years one-third of the members first nominated will retire by lot to give way for fresh members, save that it is wisely provided that a particularly useful man or woman can be elected once for a further period of three years. How one-third retires from a council of twenty will be an English conundrum; the Welsh council divides by three.

The Ministry of Health and the Parliamentary Secretary to the Ministry will be ex-officio the president and vice-president of each council, and will thus prove the coordinating link in their work. All now depends upon the quality of the councils nominated.

The Risk of Defamation in Medical Practice.—Once again an unfortunate medical man has been

accused of the foul misdemeanor of seducing a patient, and once again he has emerged triumphantly from the ordeal. Naturally there is much talk of this nature: "No medical man should ever see a female patient alone"; "A medical man should refuse attendance where he thinks there is any risk"; but such counsels are quite useless. A medical man cannot always provide that he shall never be in a room alone with a female patient—the thing is practically impossible. A medical man cannot guess beforehand that such and such a woman may turn out to be libidinous or mendacious; by the time he knows it the charge is made or ready to be made on the slightest provocation. To refuse attendance might be just such a provocation; moreover, how is a doctor to decline to attend a patient without giving a reason? And what reason should he give? It is time that the deans of our medical schools left off suggesting that safety lies in either of these procedures. It lies in being absolutely careful that professional relations are kept strictly to professional lines. No social intercourse should furnish a reason for visits being unduly long or unnecessarily private. Every attendance should be noted in a diary, if possible with a line or two detailing the reason of the visit. The patient's case, as described in the case book, should warrant the number of visits and explain the reasons for any advice given. A doctor so armed, and armed also with a good personal character on his own side, runs little risk. Lastly doctors should cooperate for their mutual defense, and at the first breath of calumny should place the conduct of their side in the hands of a competent lawyer. Here in England the Medical Defense Union and the London and Counties Protection Association are two strong and wealthy bodies, having the command of good legal advisors, and few, if any, slanderous or blackmailing charges have been made successfully against the members of either body.

Presentation to Sir William Osler.—Sir William Osler, on the occasion of his seventieth birthday, has been presented by a large group of admirers with two octavo volumes of essays written by pupils, colleagues, and friends in all parts of Canada, the United States, and England. Student in Toronto, London, Vienna, and Berlin, professor in Montreal, Philadelphia, Baltimore, and Oxford, his brilliant career as a man of learning has been almost eclipsed by his fame as the personal and attached friend of hundreds of colleagues.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, July 22, 1919.

Child Welfare Work in Belgium.—In looking over the work which has been done for the children of Belgium who have suffered by the war, one is struck by the systematic way in which the women, assisted by the Government, have managed the situation. Belgium did much for the children before the war, as the movement organized by M. Jules Le Jeune was started as early as 1890 and had gained more than double force in 1914. The war, however, revealed the exact condition of every family in Belgium, and the overwhelming interest manifested from every corner of the world for the children of the gallant little nation which was almost wiped off the face of the earth by the first stroke of the German sword, spurred the women on to continue the good work which would preserve the race. The country homes, where the children can live for two or three months in the summer and be strengthened by the country air, form one branch of the work which is proving of the greatest benefit to the little ones, and the Belgian women are making earnest appeals for funds that these homes may be purchased and made permanent institutions.

Comtesse Louise d'Ursel is among the women who have been giving their services to the children throughout the war, and, seeing what a benefit the work has been to her country, she is striving to make the people see the necessity of continuing to help in the general scheme of putting all the work on a scientific basis. One of the fine old châteaux of Belgium was turned over to her in the early days of the war and is an ideal spot for weak children to pass the summer months. Now that it is for sale she is urging the Government to buy it. It is situated at Dongelberg, about forty kilometres south of Louvain. More than 3,500 children have been cared for there during the war. At present 170 children, from 6 to 14 years of age, who lived for four years under German oppression, are there for their first summer outing. Teachers are employed to give them a few hours' schooling each day, but they are there primarily for the benefit of their health, and the improvement of their minds, though not neglected, is only a secondary consideration. The children always arrived at the château looking tired, with the strain of the war distinctly marked on their faces, but within a week their faces brightened and their happiness was restored. It was rather pathetic to note that in this group of 170 children none had leather shoes.

The house is now arranged for the care of 450 children and more beds can be installed if necessary. The Queen of the Belgians visited Dongelberg last week, when the children arranged a special fête for her. She showed great satisfaction at seeing the children so well cared for and expressed the desire that the work should be continued. This is only one of the country homes temporarily given over to the Government for the little girls. I visited a mansion at Mazy where 106 children are cared for and are given the benefit of two months in the country. The house at Mazy forms a part of the chain of Colonies for children near Namur and was given for the duration of the war.

American Red Cross Activities.—A statement, showing that the American Red Cross is continuing its activities in France, contrary to an unauthorized report that the organization was about to get out of the country at once, is issued by Lieut.-Col. George H. Burr, American Red Cross Commissioner for France. He states that the American Red Cross is readjusting its organization so that its main effort in Europe will be concentrated as a relief organization. Based on indications that a great number of American troops will be removed from France more rapidly than was expected, the Red Cross is taking steps toward eliminating activities no longer required. Services rendered the A. E. F. during hostilities and immediately afterward are now considered as no longer essential.

Although many activities have been discontinued, the Red Cross is continuing home service for the American soldier and his family and relief work for civilians in the devastated areas of France and Belgium. Line of Communication canteens will remain in operation until troop movements no longer require their services. The Red Cross expects to withdraw from its French canteens by the end of next month. To-day the Red Cross suspends all canteens for the exclusive benefit of officers, and gives up participation in all officers' clubs and hotels, except the Officers' Hotel in Paris, which it will operate until the end of June, and such clubs and hotels as the officers themselves may wish to operate until the present leases expire.

After to-day one Red Cross worker will be left with each combat division for searching home service and home communication. The miscellaneous supplies to Army units will be stopped except in case of serious emergency. Red Cross participation has been withdrawn entirely from all hospitals where its work was finished, but will be continued in other hospitals. The photographing of American graves is being carried through to completion. The readjustment of activities, which has been approved by the Commander-in-Chief, A. E. F., so far as its military aspects are concerned, means that the American Red Cross will remain in France to continue its relief work with the American Expeditionary Forces and with repatriés in the devastated regions of France and Belgium.

4. A Plea for the Early Administration of Atropine in Pneumonia.—Alexander Sterling emphasizes the point that influenza patients should be treated as pneumonia patients from the start. He states that clinicians have come to realize that the administration of digitalis should be begun early, since it takes from two to three days to digitalize the heart. When the patient is once under the influence of this agent the dose can be increased or diminished according to the conditions present. In the same way atropine should be administered early to atropinize the system. In the recent epidemic of influenzal pneumonia all the pneumonias the writer has seen have started with vasomotor relaxation, as was also proved by all the pathological reports from camp and civilian pathologists. Hare states that "during the presence of a case of pneumonia, typhoid, or other severe disease, belladonna should be kept in the house and administered freely if collapse or vasomotor relaxation suddenly asserts itself." It is the writer's practice to administer from 1 150 to 1/100 grain of atropine or five to ten dops of tincture of belladonna to atropinize or belladonnize the system. He treats all influenza cases with quinine hydrobromide or dihydrobromide. Three 5-grain capsules are given night and morning with a glass of hot tea or whiskey (one tablespoonful) until the temperature becomes normal. If the temperature is a high one a capsule is given every three hours through the day, disregarding the deafness or chinchonism symptoms. Usually in two days the temperature drops. To children quinine was administered in suppositories of cocoa butter, the dose being regulated according to age. Digitalis, atropine and cocaine were also used from the start.

℞ Pulv. digitalis .....gr. 1
Atropine sulphate .....grs. 1 100—1/150
Cocaine hydrochloride .....gr. $^1/_2$—$^1/_4$
Strychnine sulphate .....gr. 1 30
One capsule four times a day.

To children digitalis and belladonna were administered in tincture form separately so as to be able to increase or decrease the dose as needed. Alkaline drinks were given from the start. Among eight hundred cases or more of influenza in private practice the writer believes many cases of pneumonia may have been checked in their incipiency. In those patients in whom pneumonia developed the symptoms were not alarming and they made prompt recoveries under the definite treatment of S. Solis-Cohen, that is, adding to the quinine the systematic use of pituitrin in one c.c. dose every three hours, more or less, to keep up the systolic pressure and prevent tympanites, and increasing the digitalis according to the indication of the diastolic pressure and respiratory rate. Among about 120 cases of clinically pronounced pneumonia, eight patients died, including two who were moribund when first seen.

7. Gastric Cell Primary Atrophy.—Anthony Bassler divides achylic conditions of the stomach into: (1) those in which it seems to be normal in the individual, has always been and will be present throughout the life of the person, and in whom it has not and most probably will not affect the general state of health or ever cause local symptoms; (2) the psychologic cases, such as fear of the passage of a stomach tube, or the effect of depressing emotions; (3) reduced state of general body from fevers and senile conditions; (4) endocrine or hormone disturbances of which little is known, and (5) pathological conditions of the stomach glandularis in which the secreting ability is destroyed by disease of the essential elements, namely, the acids and central cells. To the latter the term atrophic gastritis should be given, a far better term for it than to designate it as achylia gastrica, because it expresses pathology instead of only a symptom. He has made pathological studies of the gastric cells of the stomach glandularis on the cadaver and such specimens as were obtainable at operation continued over a period of three years from which he draws no definite conclusions; he offers, however, the following suggestions in the hope of stimulating interest and further study: (1) These studies that suggest essential cell atrophy in the stomach is quite a common condition. (2) Cellular atrophy can be a true primary atrophy; and these instances should be dis-

tinguished from the forms secondary to chronic gastritis. (3) In primary cell atrophy the destruction is, in all probability, due to toxic effects from local infections gaining lodgment in the spongy glandularis or from bacteria culturizing in the stomach glandularis or stomach contents. (4) The bacterial studies of test meals are important in this connection, the organisms, particularly when actively motile in the test meals, being significant. (5) Distinction should be made between the pathogenic and fermentative organisms in test meals, not only because of an explanation of the achylia, but because of the suggestion that focal infection probably exists somewhere in the body. (6) Vaccines made from test meals are of no benefit in the cases, either subjectively or objectively, the removal of the focal infection being more important for benefit to the subjective symptoms as well as to the body in general. (7) With the subjective stomach symptoms alone the old method of treatment with gastric lavage as an addition to the lactofarinaceous diet and alkalis and pancreatic preparations proved to be the best treatment, although in no case was there any return of normal acid or proenzymes. (8) When primary cell atrophy has taken place, the loss of gastric juice secretion is as permanent as when the atrophy is secondary to a chronic gastritis.

8. **Gastrointestinal Disturbances in Pernicious Anemia.**—Julius Friedenwald and T. H. Morrison present a detailed report on seventy-six cases of pernicious anemia, in fifty-seven of which the gastric contents were examined. In 42 of these there was an absence of gastric secretion; in 11 the gastric secretion was diminished, and in 4 it was normal. In the 42 cases in which there was an absence of gastric secretion, the total acidity ranged between 5 and 16. In the 11 with diminished gastric secretion the total acidity ranged between 18 and 41, free hydrochloric acid between 5 and 12. In the four with normal digestion the total acidity ranged between 44 and 65, free hydrochloric acid between 32 and 44. The gastric secretion was examined in 11 patients presenting an absence of free hydrochloric acid during the period of improvement in the state of the blood as well as of the general health; in none did the secretion return during the period of apparent recovery. The writers also examined six cases of pernicious anemia according to the Rehfuss method of fractional analysis. There was in all a low total acidity ranging between 10 and 15 with an entire absence of free hydrochloric acid in every stage of the digestion. The Wolff-Junghaus test always presented low protein values, thus differentiating this condition from gastric cancer. From a study of these 76 cases of pernicious anemia the writers conclude that it is evident that a large proportion of these cases are attended with gastrointestinal disturbances as well as with absence of gastric secretion; there is present an achylia gastrica in about 74 per cent. of the cases; in 19 per cent. there is a marked diminution of the secretion, and in about 7 per cent. it remains normal.

2. **Cerebrospinal Fever. Remarks on Its Epidemiology, Prevention, and Clinical Features.**—J. Dorgan gives the results of an investigation of a large epidemic of cerebrospinal fever at an X Garrison in March, 1916, and of further investigations carried out at other stations in association with Professor C. Samut, Captains Walter Scott, R. R. Armstrong, Napier, W. J. Tulloch, S. Trevor Davies, and E. G. Pringle. He states that at an early stage of the epidemic attention became directed to the close relationship between patients definitely diagnosed cerebrospinal fever and certain other patients suffering from indefinite febrile symptoms. The difference in the two forms of illness is in the degree and intensity rather than in the fundamental characters of the symptoms. It was decided to test obscure cases found in association with the genuine disease. Meningococci were found in the spinal fluids of many patients whose symptoms would not ordinarily have suggested meningitis. Suspicion was at first aroused as to the relationship between the above types of illness, not only by the similarity of the symptoms, but also by the manner in which they were found associated in billets, tents, barrack rooms, and regiments. The writer argues the existence of the unrecognized cases from both circumstantial evidence and statistical data. The latter show that in connection with each outbreak of cerebrospinal fever there is a coincident and proportionate outburst of cases of pyrexia of uncertain origin, the symptoms of which are compatible with those found in cerebrospinal fever. Many cases of cerebrospinal fever escape detection not only because they are not suspected clinically but also because they fail to be tested by lumbar puncture, or if they are tested by lumbar puncture, modern bacteriological methods frequently fail to demonstrate meningococci, particularly in early and irregular cases. It often happens that symptoms which are at first characteristic subside rapidly and before time has been found to perform lumbar puncture the whole clinical picture has altered and puncture is not performed. The failure to puncture must occur much more frequently in civil practice and in sporadic cases, where each patient is not under particular observation. The prime importance of the unrecognized cases is the part they play in the spread of infection. It would appear that indefinite cases, which often pass unrecognized, are in reality the more numerous, and that comparatively few progress to the stage where the symptoms are unmistakable. The writer also calls attention to the fact that the effects produced by a given dose of meningococci depends on the susceptibility of the patient rather than on the virulence of the organism, because the infection received from an acutely severe case may result only in a mild and indefinite illness in the person next infected, and, on the other hand, a patient with a mild illness may reproduce a most virulent infection in another. There is no evidence at X Garrison to show that carriers convey active infection. The statistics as to carriers are conflicting and inconclusive. Their isolation is impracticable and unjustifiable. At X Garrison 520 carriers were isolated for varying periods up to four months. Of these it was found that at least 150 were not carriers at all. If carriers were capable of carrying infection it seemed extraordinary that each of these soldiers escaped infection when surrounded by four hundred virulent carriers. It is well known that carriers practically never develop the disease. This has been negatived at X Garrison, because one known carrier contracted the disease whilst employed as a nurse in the cerebrospinal fever wards. The figures at X Garrison show that a low carrier index may coincide with a high case incidence, and *vice versa*, and might be taken to indicate that cases produce carriers but not carriers cases. Carriers are found in all communities in larger or smaller numbers. In order to establish a case in favor of a carrier having caused the case, it is necessary to prove that the carrier, found as a contact, is actively pathogenic and different from the numerous other carriers universally present, or, that the proportion of carriers found among non-contacts is comparatively small compared with the number found among actual contacts of the patients. No one has attempted to show a difference between pathogenic and non-pathogenic carriers. Neither have any statistics been produced to show a difference in the percentage of carriers among contacts and non-contact carrier groups. The statistics in reference to the bacteriology lead the writer to conclude that neither the failure to find organisms on direct examination, nor a negative cultural result, can be relied upon to exclude a diagnosis of cerebrospinal fever. Recent work has thrown considerable doubt on the long established belief that meningococci pass directly through the nasal mucous membrane to the meninges. In many cases certainly, the blood is infected prior to the cerebrospinal fluid, which apparently often remains free of infection

throughout. The possibility of failure in detecting a carrier would appear to be at least 20 per cent. judging by the writer's examination of the results of repeated swabbings of chronic carriers, where intermittent negative results were followed by positive findings. In discussing prophylaxis, the writer states that the infection of cerebrospinal fever is not to be feared under good condition of housing and ventilation. The early isolation of mild and severe cases and the provision of free ventilation compulsory, and with sufficient warmth during the time of seasonal prevalence, constitute the most effective means of prevention.

3. An Investigation of the End Result in One Hundred and Twenty-four Cases of Blood Transfusion.—W. Grant Waugh records the results obtained in a series of blood transfusions carried out in a base hospital in France between November, 1916, and October, 1918, with a comparative table of the results in cases of as nearly as possible identical nature, treated before blood transfusion was available. The method employed was that of indirect transfusion by Vincent's paraffin coated tube, because at that time the citrate method was not available. Compatability was established at first by direct comparison of the bloods under the microscope and later by obtaining Group IV donors by the convenient microscopic method introduced by Lee. The main indications for blood transfusion in a base hospital are, according to the writer: (1) severe secondary hemorrhage, (2) preliminary to high amputation of the thigh or arm, (3) certain cases of pyemia. The primary indication for transfusion, surgical shock, is much less frequent at the base than at clearing station. As a result of his experience he could not subscribe to the view that secondary hemorrhage is rarely accompanied by shock. The amount of blood employed was usually 600 c.c., but amounts of 900 to 1,200 c.c. have been injected as the condition of the patient demanded. The donor's blood pressure usually fell about 10 mm. Hg., but recovered to normal within an hour. Incompatability was met with on three occasions. In two of these transfusion was abandoned, no ill effects persisting; they were probably due to faulty comparison of the bloods (these cases were not included in the series). The third case occurred in a man suffering from pyemia who was being transfused for the third time. In addition to emphasizing the necessity for ascertaining the symbiosis of the two bloods before every transfusion, this case seems to indicate that incompatability may develop as a result of multiple transfusion. Incompatability usually declares itself after 10 c.c. of blood have been injected; in this case injection had proceeded for a considerable time before any symptoms appeared. The explanation suggested by Bond is that "a definite alteration has been found to occur in the direction of increased hemagglutinin content of the blood in the interval between the two transfusions," and that this was responsible for the unfortunate result. Of 52 cases of secondary hemorrhage, with ligation of the main artery, that were transfused 35 recovered, and 17 died, a death rate of 32.7 per cent., while of 52 similar cases not transfused 28 recovered and 24 died, a death rate of 46.1 per cent. Of 14 cases of secondary hemorrhage following amputation of a limb, transfused, 10 recovered, and four died or a death rate of 28.5 per cent.; of 14 similar cases not transfused, seven recovered, and seven died, a mortality of 50 per cent. Of 39 cases of sepsis or gangrene, with amputation of the limb, which were transfused, 35 recovered, and four died, a death rate of 10.2 per cent.; of 29 similar cases not transfused, 20 recovered and nine died, a mortality of 31 per cent. Of 19 transfused cases of pyemia, 12 recovered, and seven died, a death rate of 36.8 per cent. In the entire series the mortality among the transfused cases was 25.8 per cent., while among those not transfused it was 42.2 per cent. The writer therefore believes the number of recoveries in these very severe cases justifies an extension of the method as a therapeutic measure and thinks it reasonable to hold that it should come into general use in civil practice as a preliminary to any severe operation.

4. Mastoiditis.—Adair Dighton contends that the term "suppurative otitis media" is a misnomer, as in every case the disease starts in the mastoid antrum, and the suppurative otitis media is only an outward and visible sign or symptoms of this invisible disease. He has taken swabs from the bottom of the mastoid antrum in fifty consecutive cases of operation for suppurative otitis media, and in every one pathogenic micro-organisms were found. During his period of officer in charge of the aural center at Blackpool, 4,148 cases passed through his hands, 90 per cent, of which were cases of suppurative otitis media. They were treated daily by all known methods, with no good results of any kind. The writer took particular note of all operated cases, and found that among 53 cases only nine could justifiably be called healed. Of these nine, five underwent a radical operation, and four a modified mastoid, or Health operation; in the former cases the best hearing was 7/17 watch, whilst in the latter the hearing was practically normal (15/17). Of the 44 unhealed cases, 33 had widely patent Eustachian tubes. This was interesting as one rarely has trouble with the tubes after the Health operation. The writer considers that the radical operation is hardly justifiable save in very exceptional cases. He mentions two variations in the Health technic which he finds useful. As a preparatory dressing he finds that iodine two per cent. in carbon tetrachloride is by far the nicest and does not blister or irritate the skin. The flap which he has described in the Annals of Otology (June, 1916), he finds most useful. After one has used it in a few operations it can be so fashioned in nearly every case that the stitch which holds it closed the post-auricular wound and obviates the use of skin stitches. One skin stitch at most is all he ever uses. As an after dressing he prefers ribbon gauze soaked in freshly prepared eusol for a week, until the flap stitch is removed, and then instillations of rectified spirit with no syringing of any kind, as the drier the ear is kept the better.

British Medical Journal.

2. War Lessons as Applied to Civil Practice. Robert Sanderson.
3. Note on Re-amputation. A. E. Chisholm.
4. Accidental Transference of the Malarial Parasite in the Course of Transfusion. Alfred S. Gubb.

2. War Lessons as Applied to Civil Practice.—Robert Sanderson agrees with others in describing all gunshot wounds as potentially septic wounds and states that septic wounds are by no means uncommon in civil life. For instance, abrased, contused, lacerated, incised, or punctured wounds received by workers on the soil, especially made soil containing manure, bicycle and motor accidents, and street accidents generally, in so far as they are potentially septic, resemble the wounds of war, and should be treated on the same lines. Antitetanic serum should be administered as a routine practice in wounds of this kind, and it is the duty of the sanitary authority or the Government to provide this serum. In the prevention of the development of bacterial infection in wounds of this class the problem is how best to aid the natural defences of the body, which are in the main two in number, namely, (1) the antipyretic power of the blood serum, and (2) the phagocytic action of the living cells. To accomplish this it is generally recognized that the sooner a wound is excised after the receipt of an injury the more certainly is infection avoided. The procedure in superficial wounds, which do not extend beyond the deep fascia, is to shave the skin and swab it with iodine or a 5 per cent. solution of picric acid in spirit.

The tissues are then infiltrated with novocain and adrenalin. The wound itself is wiped out with a swab soaked in either iodine or picric acid solution, and dried. The ends of the wound are clipped so as to put the tissues on the stretch, and with a sharp scalpel the wound is excised completely at a distance of one-third to one-half an inch from the wound surface. In deep wounds total excision may be anatomically impossible, but the skin and more superficial parts can be excised, and injured muscle removed, loose bone fragments picked out, and a careful toilet of the wound made under a general anesthetic. If immediate primary suture is not employed—and in the majority of cases this is too risky—the wound is packed with gauze well soaked in flavine; then in forty-eight hours, if the bacteriological findings are favorable, the wound is sutured carefully so as to bring all surfaces into contact and leave no cavities. There are two classes of wounds in which primary or immediate suture has been found advisable —namely, in wounds of the scalp and wounds of the knee joint. The writer submits statistics of 150 consecutive cases of delayed primary suture which were performed in May, June, and July, 1918, at a base hospital in France. Delayed primary suture was employed in 11 cases of compound fracture, and with one exception that all healed *per primam*. As to the other 139 cases, failure occurred in 13 instances and partial failure in five cases. The failures occurred in cases in which streptococci were present or massive infections by *Staphylococcus aureus*. The writer points out that the war has also revolutionized our ideas in regard to antiseptics. When a wound is really septic, and the colonies of bacteria have penetrated deeply into the tissues of the wound, no antiseptic quâ antiseptic is of any avail. But when a wound is fresh, and has been excised wholly or in part, and is awaiting early suture, a suitable antiseptic is of value. Flavine, according to the writer, is by far the most efficient antiseptic which we possess—its peculiar quality being it is very powerful in high dilution against both the cocal and *B. coli* group and that its power is greatly enhanced in the presence of serum. In discussing transfusion, Sanderson asserts that there can be no doubt that the transfusion of human blood is the ideal method. Where, however, this is impracticable and one must resort to the transfusion of normal saline, the efficiency of the solution is greatly enhanced by adding gum arabic in the proportion of 0.9 per cent. thereby greatly diminishing the tendency of the solution to transude through the capillary walls. Another lesson which the writer states we may draw from the experience of the war is the extreme value of what we may call team work in research, diagnosis, and treatment, and he believes that this is perhaps the most important of all the lessons which the war has to teach us. The crying need of the day is the establishment of an adequate number of hospitals staffed by teams of general practitioners to which all practitioners can have access and to which they can send cases requiring clinical observation of any kind, rest, or treatment, which cannot be carried out in the sick person's home.

La Presse Médicale.

May 22, 1919.

Lichen Planus of the Mucosæ and Leucoplakia.—Brocq gives an interesting account of the confusion of these subjects in the minds of many practitioners of good standing. First, these men are obsessed by two species of false doctrine, that mucous patches are invariably syphilitic, and, second, that they are very likely to become cancerous. These statements are made with full consciousness, doubtless, that nothing is more resistant to treatment than leucoplakia. The condition known as lichen planus of the buccal mucosa—tongue and cheeks—while rare, should be known to the practitioner. The diagnosis is not difficult when there are cutaneous lesions associated, and even when isolated the peculiar lesions of lichen may be recognized on a mucous surface because of the similarity with cutaneous lesions. Moreover, there is usually no evidence of syphilis or tabagism. When one of the victims of this simple affection consults a nonspecialist he or she receives a double shock. There is the accusation of syphilis and the prognosis of cancer, and between the two the subject is completely upset. If properly advised, he comes to Paris or the metropolis, with the address of the best specialists, and, entering the office in a state of the utmost trepidation, is assured at a mere glance that he has a benign condition of such rarity as partially to exculpate the physician who made the diagnosis (although it is mortifying to know that good provincial practitioners are responsible for such heresies as the specific nature of the leucoplakic lesion and the inevitable outcome in cancer should the patient live long enough). In some cases, in order to reduce the chance of cancer, these lichen patients are sent to the dentist, who may extract certain teeth, or are told never to smoke or use condiments, etc.

Hygiea.

April 30, 1919.

Incarcerated Diaphragmatic Hernia.—Landelius describes the following case, in a boy of 17 with left incarcerated diaphragmatic hernia which came about acutely during a gymnasium stunt. The diagnosis was made by the *x*-rays, and operation was performed thirty-six hours after the incarceration. The stomach, spleen, and lienal flexure of the colon, having prolapsed through the opening, reduction became possible only after puncture of the distended stomach. The thoracic wall was sutured primarily. The patient was discharged thirteen days after operation. The hernia was purely congenital. The *x*-ray will differentiate between a large diaphragmatic hernia and eventration. A symmetrically protuberant curved line as the upper margin tends to signify a prolapsed stomach rather than an eventration. The irregularly protuberant upper margin which is believed to indicate a diaphragmatic hernia is due to prolapsed intestine, but the prolapsed stomach is a far more common find. In operating one should go through the pleura. The author gives numerous statistics. Authors differ as to the number of recorded cases, some making the total over 1000, while others limit the record to less than 700, these differences depending on the criteria used.

Hygiea.

May 16, 1919.

The Rôle of the School in the Spread of Influenza.—Zander refers to the experience of a common school in Stockholm in the fall of 1918. Of 711 pupils, 419 were attacked by the Spanish epidemic. The school comprises twenty-four departments and the morbidity of each was compared with the general city morbidity. In all but three the curves showed a parallelism quite remarkable. In these exceptions evidences of an explosion of the disease were present. From these finds the author concludes that it is not worth while to close the schools, since the morbidity is chiefly along general lines. In other words, nearly all the children had been attacked outside the school. In the small minority the disease may have spread among the pupils. In these subdivisions the disease did not spread to any extent, so the rate of infection was not in excess of the general school rate. An important conclusion is that when a child first contracts the disease at home, or elsewhere outside the school, he does not become dangerous to the other children during the early days, or, in other words, the disease is not contagious during its inception. Hence the parents should not keep their children away until they develop suspicious symptoms, when they are to be kept strictly indoors. Further, if they are taken ill in school they must be promptly sent home.

Treatment of Oxyuriasis.—Kjerrulf refers to the recommendation by Dreuw in 1910 to use basic acetate of aluminum for this affection. For the past eight years he has employed a modification of this treatment for the same condition, a dry basic acetate of aluminum in doses of 1 gram, three times daily, for the adult. This he mixed with laxatives—senna and sulphur, with the compound licorice powder of the Swedish Pharmacopœa. This treatment was kept up for four or five days. In order to prevent reinfection by the anus an ointment of thymol was employed, which also contained camphor and quinine.

Book Reviews.

THE NEW PHYSIOLOGY AND OTHER ADDRESSES. By J. S. HALDANE, M.D., LL.D., F.R.S., Fellow of New College, Oxford. London: Charles Griffin and Company, Limited; Philadelphia: J. B. Lippincott Company, 1919.

IN this volume will be found six addresses, all bearing on the relation of biology to other departments of knowledge. Medical readers will find the fourth paper, on The Relation of Physiology to Medicine, of most interest. This paper was read before the Edinburgh Pathological Club, and in it the author bears witness to the development of medical teaching and research in the best American universities; he says that (in a recent visit to America) "in place of the pompous ignorance of physiology and pathology which one meets with so often among medical teachers in Europe, there was everywhere considerable knowledge of, and enthusiastic belief in, scientific methods." This book should find a place in all medical libraries; its contents will be appreciated by all progressive physicians.

MANUAL OF LABORATORY DIAGNOSIS. Compiled and elaborated by HERMAN JOHN BOLLINGER, S.B., M.D., Assistant in Bacteriology, Johns Hopkins University. Price, $3.25. Baltimore, Md.: The Medical Standard Book Company, 1919.

THIS is a summary of the lectures given in the general course in Clinical Microscopy during the past year at Johns Hopkins University by five instructors. It is based upon notes taken by one of the students and is not intended to be comprehensive, but rather a skeleton note book upon which the student in the course may build a complete record of the information which it presents. Presented in note-book form, the language is condensed and all unessential words omitted. As an outline it is excellent, and it does not seem that the book should need all the apologies that are made for it in Dr. Miller's Preface. His statement that careful correction has not been possible is not so evident in the subject matter, which is excellent throughout, as it is in the typographical work, for the errors in that department are very numerous and occasionally confusing. The book really deserved better proofreading. As a skeleton notebook it is admirable, but it will find comparatively little demand for other purposes.

SURGICAL TREATMENT: A Practical Treatise on the Therapy of Surgical Diseases for the Use of Practitioners and Students of Surgery. By JAMES PETER WARBASSE, M.D., Fellow of the American College of Surgeons, American Medical Association, American Academy of Medicine, New York Academy of Medicine; Formerly attending Surgeon to the Methodist Episcopal Hospital, Brooklyn, New York. In three volumes, with 2,400 illustrations. Price per set, including separate desk index volume, $30.00. Philadelphia and London: W. B. Saunders Company, 1918-19.

IN the preface Warbasse states that his object has been "to place in the hands of the surgeon the means for rendering help in every surgical condition under all circumstances," which would seem to be a rather large order for a single individual. One of the author's aims has been "to inspire the reader with the spirit of originality." To the degree in which this inspiration "takes" we fear disaster to the patient rather than the conservation of his interests, for we do not look to the type of man who really needs such a work as this for new operations or for a revised technique, but to the more experienced surgeon, and it is to the younger practitioner rather than to the experienced operator that a work of this nature appeals.

Volume I contains 947 pages, with 699 illustrations. The author first discusses at length general surgical principles, surgical materials, and their preparation, anesthesia and anesthetics, preparation of the patient, and various details of operations in general, operating room equipment and technique, postoperative treatment, inflammations, nutritive disturbances, and various other kindred subjects.

Volume II, of 829 pages, with 761 illustrations, is devoted to the surgery of the head, neck, spine, thorax, breast, and abdomen. Included in surgery of the head and neck we find the special surgery of the nose, throat, and ear. The help of collaborating specialists would have added markedly to the value of this portion of the work. In the section on the thorax the author has described the usual operations, and the various methods and apparatus for intratracheal insufflation are described and illustrated; but there is practically nothing concerning the removal of foreign bodies from the lung, and throughout the section many of the lessons regarding thoracic surgery taught by the war seem to have been disregarded. The introductory pages in the section on the abdomen, on the other hand, contain much advice that is of practical importance.

Volume III, of 861 pages, with 864 illustrations, covers the subjects of hernia, the rectum and anus, the vermiform appendix, the liver, gallbladder and bile ducts, the genitourinary system, the female genital organs, and the extremities. There are also chapters on plastic and cosmetic surgery, electricity and radiation in surgical treatment, first aid, bandaging, and various other subjects. In the section on hernia the article on sliding hernia is very incomplete and needs radical revision; and the author would do well to familiarize himself with the contribution to this subject by Alexis Moschcowitz before rewriting the article. We also violently disagree with the author's conception of the rôle gallstones should play in gallbladder surgery. Their removal should be much more than a mere incident in connection with drainage and relief of obstruction, for their presence is a constant invitation to infection, and they are found almost invariably in cases of carcinoma of the gallbladder. The operation first described for anchoring the kidney is far inferior to the Edebohls method and several others that are not even mentioned; while the description of decapsulation, an operation known throughout the world as the Edebohls operation for nephritis, does not give the usual Erebohls technique but is approximately that of the operation favored by Warbasse for anchoring the kidney. The section on plastic and cosmetic surgery is well done and of real practical value.

Considering the work as a whole, Warbasse has written an excellent treatise, which will be of great assistance to the general practitioner as well as to the surgeon. Minor surgical work, the treatment of fractures and dislocations, nonoperative treatment, the indications for operation, and numerous other features are of special interest to the general practitioner. The books are marred by numerous typographical errors, some of which make the text somewhat obscure. For example, we find "effected" for affected, the "joint" of the scalpel instead of the point, while in the legend under Fig. 1458, the *superior* mesenteric vessels are labeled *inferior*. The illustrations are as a rule excellent, but there are far too many—scores if not hundreds—that serve no useful purpose and simply add to the bulk of the volumes. Such, for example, are illustrations of common instruments, such as bandage scissors, and articles in household use, such as icebags and bedpans. This profusion of illustration is carried to the extreme in the third volume, where the number of illustrations actually exceeds the number of pages in the book.

THE MEDICAL CLINICS OF NORTH AMERICA. Vol. II, No. 4, January, 1919, New York Number; Vol. II, No. 5, March, 1919, Boston Number. Price, $10.00 per year. Philadelphia and London: W. B. Saunders Company.

THE New York Number of this publication contains presentations by fourteen representative New York physicians. The most interesting and important are probably Lamb's discussion of Non-hemolytic streptococcus, Endocarditis and DuBois' presentation of the Basal Metabolism in Thyroid Disease. But all the articles are of value and any selection would probably depend chiefly upon the special interest of the one making the choice.

The Boston Number includes contributions from seventeen men upon widely diversified topics of immediate interest. The most important, we feel, is Minot's presentation of four cases with enlarged spleens. Rosenau's contribution on Fallacies in the Diagnosis of "Ptomaine Poisoning" should be read by every physician who has made that diagnosis.

The idea of obtaining material for these numbers from the various medical centers in this country is an excellent one, and this publication is sure to be widely read and appreciated.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Fifty-third Annual Meeting, Held at Spring Lake, N. J., June 24 and 25, 1919.

DR. THOMAS W. HARVEY OF ORANGE, PRESIDENT.

First Day—Tuesday, June 24.

The Importance of the Early Diagnosis and Operative Treatment of Fracture of the Skull, with Report of Cases.—Dr. WELLS P. EAGLETON of Newark, in presenting this paper, stated that there were two points that he wished particularly to make: First, the aseptic treatment of wounds, and, second, the discovery by an English surgeon that excision of the wound would allow it to be converted into a primary wound and closed, and, later, the application of this treatment to cranial injuries. He had been impressed with the frequency with which linear fractures of the skull were overlooked, the patients later dying from a latent infection of the meninges due to a small, unnoted avenue for the entrance of germs by means of a slight crack fracture under the scalp wound. He believed that every case of possible fracture of the skull or of wounds around the skull should be routinely incised, so that the skin flap could be pulled apart and the bone exposed. This should be done within six hours of the receipt of the injury, as before that time the germs do not begin to multiply in the tissues. The principles underlying the diagnosis should be routine neurological examination in all cases of suspected fracture; routine examination of the blood pressure; routine ophthalmoscopic examination; lumbar puncture; and *x*-ray examination. If every hospital would require these examinations to be made routinely, the same as the temperature and pulse are noted, the author was convinced that many more such cases would be saved. In simple fractures the early relief of pressure and prevention of sepsis would enable nature to take care of the condition. Dr. Eagleton considered a low disatolic pressure a contraindication to operation. In such cases nothing except what was absolutely necessary to control hemorrhage should be done until the diastolic pressure had come up. The fracture having been located, the area of infected bone should be excised, so as to allow of its conversion into a simple fracture, with primary closure of the dura.

Dr. ANDREW F. MCBRIDE of Paterson remarked that in military practice one was able to have all the things necessary, such as proper *x*-ray work and neurological examinations, to carry out routine work, but that in many of the civilian hospitals these things were not easily obtained. He expressed the hope that the paper of Colonel Eagleton would awaken all the men to the importance of having proper examinations made in all the cases of skull injuries.

Dr. JOHN B. ROBERTS of Philadelphia said that he wondered how Dr. Eagleton had been able to get so many postmortems. He believed that a great cause of difficulty was the fact that most surgeons did not know enough neurology, and that most civilian surgeons did not know enough surgery to do the good work shown by Dr. Eagleton. He did not think that blood-pressure examinations were made frequently enough. He also stated that the same was true of examination of the eyegrounds and the early sterilization of wounds. He thought that there was too much done by younger men before they had seen their chief, because the work done by subordinates was not always aseptic.

Dr. JOHN C. MCCOY of Paterson emphasized particularly two points that Dr. Eagleton had brought out: the proper cleansing and dissection of the scalp wound, and spinal puncture as a therapeutic measure. He thought that too much stress need not be laid on sterilization, because it was the surgical treatment of the wounds that determined the outcome, so far as infection was concerned, rather than the method of sterilization.

Dr. CHARLES A. ROSEWATER of Newark stated that a man, in order to be sufficiently comatose under alcohol to have his case mistaken for one of fracture of the skull, should show an alcohol content of his blood. If 10 c.c. of blood had been withdrawn and examined in a case reported by Dr. Eagleton the diagnosis would have been made, and they would not have believed that it was a case of alcoholism. Nevertheless, it should be remembered that a man can be drunk and have a broken head at the same time.

Dr. BRITTON D. EVANS of Greystone Park emphasized the value of lumbar puncture in diagnosis and in treatment. Its value was shown not only in the active work immediately after accident, but also in the end results and in medicolegal considerations.

Dr. EAGLETON, answering the question of Dr. Roberts, said that he believed that physicians could have a postmortem on nearly every patient that died under their care, if the family were impressed with the fact that the doctor had sincerely tried to help the patient, and that he was willing to give up any amount of time in order to ascertain the real cause of the death, emphasizing the scientific value of the information to be gained in this way.

The Value of the Electrocardiograph.—Dr. JOSEPH SAILER of Philadelphia said that the principal value of the electrocardiograph was in enabling one to determine which side of the heart was doing the most work. He considered the reaction extremely difficult, but most clearly shown in the standing position. Even slight differences in action between the two sides of the heart, he said, were often well shown in the tracings. Right preponderance meant mitral; and left, aortic disease. In congenital heart disease the preponderance was usually right. Left preponderance might suggest renal as well as cardiac trouble. In the author's opinion, other methods of diagnosis had not been in the least displaced by the use of the electrocardiograph. Indeed, their necessity had been greatly increased and physical signs could be understood much more clearly since the introduction of this aid, which was only one method of diagnosis. He expressed the hope that all available methods would be used and new ones discovered.

Gonococcemia and Metastatic Gonorrhea. — Dr. HYMEN I. GOLDSTEIN of Camden sounded the warning that before undertaking treatment for metastatic gonorrhea one should make sure that the arthritis was of gonorrheal origin. He stated that this could be ascertained by the history, the age and sex of the patient, the complement-fixation test, and smears from the urethra and after prostatic massage. All these cases, he remarked, had a focus of infection somewhere—usually in the prostate or seminal vesicles in the male, and in the tubes and ovaries in the female. Unless these foci of infection were treated, the disease could not be eliminated. The best method of treatment, aside from the rest and the local treatment, he considered to be the administration of large doses of gonococcic serum—up to 50 c.c. This was best given in doses of 10 to 15 c.c. on successive days. The action of the serum could be enhanced by the continued administration of mixed polyvalent vaccines, in doses varying from a quarter of a million to two, three, or even four millions in the more subacute or chronic cases. The careful administration of fresh vaccine in large doses seemed to do more good than the serum alone. The preferred method of treatment was a combination of the two. On the eighth to the tenth day following the administration of the serum, there was produced an anaphylactic reaction. This could be best controlled by giving a 1:1000 solution of adrenalin, in minim doses, every four to five hours; and $\frac{1}{100}$ to $\frac{1}{150}$ of a grain of atropine hypodermically. Large doses of alkalies could also be given. If the gonorrhea remedies did not then improve the condition, one must keep on with the local treatment, prostatic and vesicle massage, etc. Failure to improve might also be due to inadequate dosage of antigonococcic serum and antigonococcic vaccine. The intravenous administration of the serum, the author thought, might act more promptly in certain cases. One should not forget that enlarged tonsils, bad teeth, and infected sinuses constituted the most frequent causes of an arthritis, and that this source of infection might be overlooked in the presence of a urethritis.

Dr. H. LOWENBURG of Philadelphia, Pa., stated that the most frequent type of gonorrheal infection met with in the young was vaginitis, which, in spite of the most painstaking and thorough preventive measures, would obtain access to children's institutions. He believed that no one could tell when a case of vaginitis was cured. He thought that no case should be even tenta-

tively discharged as cured unless there had been neither discharge nor positive smears for at least four successive weeks, during which no treatment had been employed. He considered vaccines of doubtful value, and stock vaccines as absolutely useless, probably because most of them were made from adult gonococci, which are not identical with those found in the child. Dr. Lowenburg considered local treatment the most important and valuable, although not curative.

Dr. EMANUEL D. NEWMAN of Newark referred especially to keratodermia blenorrhagica, a rare dermatological condition associated with gonorrhea complicated by an arthritis unassociated with high temperature. He quoted the literature on the subject, and described at great length the gross and microscopic appearance of the lesions. He further stated that the prognosis depended entirely upon the associated conditions; and that if recovery took place, there occurred a spontaneous involution of the dermatological condition.

Dr. LOUIS L. DAVIDSON of Newark remarked that gonorrhea, instead of being a merely local infection, might become a specific blood disease. This, he said, was only lately beginning to become recognized by the medical profession. A focus of gonorrheal infection in the seminal vesicles would frequently produce a train of vague symptoms producing a condition commonly known as sexual neurasthenia. These cases he considered very difficult to cure, great patience and much time being required, seminal vesiculotomy sometimes being required before a cure could be effected.

Dr. OTTO LOWY of Newark stated that physicians should never discharge a patient with a Neisserian infection until he was physically and from the laboratory standpoint cured. The seminal vesicles should be stripped, and the complement-fixation test should be negative for a number of times.

Dr. F. WARD LANGSTROTH of Ridgefield Park stated that recent researches had shown that the vagina of vulva was not the site of gonorrheal infection, the real sites being Skene's glands, possibly the urethra, Bartholin's glands, and the cervix. About 90 per cent. of the cases, he said, were in the cervical endometrium. He believed that the only means of eliminating gonorrhea in the female was to enucleate the endothelium of the cervix, the tissue of the female that harbored the germs permanently.

Dr. CHARLES A. ROSEWATER of Newark stated that the diplococcus found in the vagina of the child, although it looked like and stained like the gonococcus, was not the same, and could be differentiated from that organism only by the cultural method.

Dr. GOLDSTEIN had not found that the focal reaction following the use of vaccine as a diagnostic agent was a conclusive method of diagnosis. He said that involvement of Skene's and Bartholin's glands was no doubt included in the term vulvovaginitis.

The Address of the President.—Dr. THOMAS W. HARVEY of Orange, in this address predicted that the men coming back from the other side would find themselves unfitted to work in the old way; that they would expect recognition as experts along the lines on which they had been working abroad; and that in the smaller places little groups would be formed, similar to the diagnostic groups in the larger cities. He thought that it behooved those who had remained at home to be receptive to the new ideas and suggestions, and anxious to bear their share in the introduction of new methods. With this in view, he recommended that a new standing committee should be established in the society, whose functions should be those of an active agent in forwarding the welfare of the profession. Its duty should be to complete the organization of the doctors in New Jersey, inducing those not already members to join the county societies. It should also be the representative of the society to confer with employers, insurance companies, etc., on all matters relating to the profession, and take the initiative in looking after the doctors' interests. In facing a new form of contract medicine, one with the backing of the State, he deemed it necessary that they should see that the individual doctor was not imposed upon. He believed that a united profession could dictate the terms on which medical services should be rendered. A third function of this committee was to see that if the State provided for the medical care of people with limited incomes, it should also provide for that of people with no income, and not expect the medical profession to do it. Dr. Harvey thought that the committee should be composed of the younger and more aggressive medical men.

Oration in Surgery.—Major ELLSWORTH ELIOT, JR., of New York City based his remarks on observations made during the Chateau-Thierry and Argonne campaigns. He was also able, after the signing of the armistice, to observe the results of treatment at the front, in a group of five hospitals in the neighborhood of Tours. In speaking of joint injuries, he stated it was his opinion that it did not make much difference, if the joints were thoroughly cleansed of infectious material, whether they were sutured, left open, or drained. The infection was not developed usually from without inward, but from within outward, from material left in the joint cavity. For the transportation of men with leg injuries, the Thomas splint proved the most satisfactory. He had observed at autopsy three or four cases in which the ventricular cavity was filled by a blood clot, and stated that he felt that if these clots could have been removed, the patients might have recovered. Referring to nerve injuries, the speaker mentioned that he had been informed by a surgeon connected with a hospital in Chicago that he had had eight hundred cases in which primary suture of an important motor nerve that had been divided had been neglected. In closing his oration, Dr. Eliot referred to the wonderful work that had been accomplished by the members of the medical profession of New Jersey, not only those who had gone to the front, but also those who had remained at home. In some respects, he considered that those who had remained behind deserved more credit than did those who had gone abroad; because all would have gone, had they had the opportunity, and those who remained behind had most of the drudgery. He thought that the society should be highly complimented on the part that many of its members had played in the late war.

Second Day—Wednesday, June 25.

The Medical Service in a Base Hospital.—Dr. MARTIN J. SYNNOTT of Montclair described the organization of a military hospital and the administration of the medical service, referring especially to the diseases seen most frequently in the army, which were as follows: Effort syndrome, thyrotoxicoses, status lymphaticus, meningitis, tuberculosis, pneumonia, empyema, and epidemic influenza.

Major A. F. MCBRIDE of Paterson stated that there had been a great deal of criticism against some of the boards, who had rejected men believed by others to be physically fit; and numbers had been passed that the surgeons at Camp Dix did not consider fit for any service of a military character. These men were soon detected, and either put at minor work or discharged on certificate of disability.

Dr. JOHN C. MCCOY of Paterson referred to the fact that the American troops had been lined up back of Chateau-Thierry for four weeks before the offensive opened, and were more or less constantly under shell fire during that time, there being large numbers of gas shells sent over. He had observed the interesting fact that within the first twenty-four hours there were found seventy-five self-inflicted wounds; and that of the 1,120 that came down gassed in the second twenty-four hours, 90 per cent. were put back into the line the next day, as shell shock cases of a mild type. This observation bore out what Dr. Synnott had said concerning the emotionally sensitive type of patients.

Dr. HARVEY M. EWING of Montclair remarked that Lewis had included the gas cases in one of his classifications of the neurocirculatory psychasthenia, but that at Lakewood not so very many such cases were seen in the hospital.

Dr. DAVID A. KRAKER of Newark said that they had had two such cases in the hospital with which he had been connected. He mentioned a class of patients who, being emotionally sensitive and under excitement, believed that they had been gassed; whereas, in reality, they had merely been thrown down by the concussion of high-explosive shells and had inhaled the emanations from them. There was another type of cases, in which the men had inhaled a highly irritating gas in such

small quantities that it apparently was not noticed at the time. At the end of about thirty-six hours, after their wounds had received surgical attention, they would begin to develop a violent type of respiratory inflammation. Dr. Kraker believed that those who were considered as shell-shocked really believed that they had been gassed; and some had really felt the irritating effects of inhaling the high-explosive emanations, but had not received actual gas poisoning.

Raynaud's Disease.—Dr. Henry Pelouse de Forest of New York presented a clinical study of a number of cases, with illustrations of gross and microscopic lesions and some suggestions as to the etiology and treatment of the disease. He stated that the disease was considered very rare, Raynaud himself having reported only five cases in his original communication, and no one author in a bibliography containing several hundred titles having reported more than one or two cases. Dr. de Forest himself, however, had seventeen typical cases coming under his own personal observation. He stated that this was the only series of cases of which he had any knowledge in which there was a definite record of the lesions that had been found by Raynaud. He thought that the cause of the disease must be located somewhere in the body where the nerves of the two symmetrical parts affected met—whether in the brain or in the spinal cord was not definitely determined. While in a series of sections the spinal cord appeared distorted, he admitted that this distortion might have been caused by changes extending from the brain downward. In nearly all his cases there was a history of continued irritation from one cause or another. In three of the cases, this irritation was caused by metallic copper. Three had to do with pigment. Treatment had been rather successful in all of the cases in which the patient was seen at a relatively early stage in the disease. Having adopted the hypothesis that the condition was due to a toxemia of some kind, the logical plan of treatment was to eliminate as far as possible any poisonous material present by means of free catharsis and a continued free action of the bowels and, in addition, to try to build up the blood and the tissues by the administration of tonics. In each case in which the patient, by a systematic course of body building, had been made to gain from five to thirty pounds, recovery had taken place.

Dr. Louis G. Shapiro of Paterson thought that these cases included a rather heterogeneous group, from which could be picked out certain types, the two main ones being those with patent vessels, or cases of Raynaud's disease, and those with obstructed vessels, or cases of thromboangeitis obliterans. In his opinion, the latter consisted in an inflammatory reaction of the adventitia and media, extending through to the intima, with the production of a thrombus, which gradually ascended. The first symptom noticed was usually coldness in the toes, and subsequent flushing. The next symptom was unremitting pain, night and day. Morphine and hyoscine did not relieve them, and the only thing that did was amputation. The speaker said that the condition seemed to be limited to Russians and Poles, particularly the Jews of these nationalities; and to be almost exclusively limited to males. The condition never cleared up, but went on to gangrene and necessitated amputation. The principal physical sign was the slow obliteration of pulsation at higher and higher points.

Dr. Emanuel D. Newman of Newark referred to a case that he had had some years before, in which the cheeks and the tip of the nose were involved. He had called the condition a fulminating purpura. He requested Dr. de Forest to give a differentiation between these conditions, and to state his opinion as to whether such cases should be classified as Raynaud's disease. He also asked whether cases involving the scrotum and penis should be considered as ones of Raynaud's disease, and whether syphilis had constituted a factor in the etiology in the essayist's cases.

Dr. Frederick W. Flagge of Rockaway spoke of a case of thromboangeitis obliterans that he had first seen three years before, and which had been gradually growing worse. The patient was a Russian Jew. He did not suffer extreme pain, as a rule; but the condition was worse in the winter, and he had to wear thick shoes and stockings to protect himself against the cold.

Dr. Henry Pelouse de Forest of New York considered it possible that Raynaud's disease might merge into thromboangeitis obliterans. He believed the characteristic feature of Raynaud's disease to be that it was always symmetrical, thus differing from gangrenes produced by other causes. In none of his cases was it possible to elicit a history of syphilis; that, however, did not prove that it had not existed; because many of the cases occurred before the introduction of the Wassermann test. Five of the cases were complicated with unquestioned purpura. The case in which the cheeks and the tip of the nose were involved, he stated, was undoubtedly one of Raynaud's disease, the tip of the nose being really symmetrical, only the two sides came together.

Leucocyte Extract for the Treatment of Undetermined Infections.—Dr. G. F. Leonard of New Brunswick stated that it was not claimed that leucocyte extract was a specific for any disease, nor that it was a panacea. From the clinical evidence available, however, he had arrived at the following conclusions: (1) Leucocyte extract was harmless in localized infections, superficial and deep. (2) Its use had proved beneficial, many cases being cured, and others improved. (3) In pneumonia other than Type I, it improved the general condition, made the patient more comfortable, probably shortened the course of the disease, and decreased the mortality. (4) In any undetermined infections it was the sole biological product indicated. (5) In infections attended with high leucocytosis, such as was found in measles and influenza, the administration of leucocyte extract resulted in an increase in the number of leucocytes, and was therefore indicated. The author stated that in cases in which there was a specific serum, that alone should be used; but that in cases in which there was no specific serum, and in those in which the infection was not known, the use of leucocyte extract was particularly of value.

Dr. Bishop of New York called attention to the fact that the so-called specific treatment of disease was not so specific as it had been supposed to be, and that there was an interchange between different kinds of so-called specific treatment. He thought it possible that in this leucocyte extract the profession had found the ideal foreign protein to use when there was no particular reason for using any other.

Oration in Medicine.—Dr. Thomas McCrae of Philadelphia made a plea for more thoroughness in the instruction of students. He suggested that medical men take stock of themselves, to see how well or badly they were doing their work. One should not be contented to make a diagnosis or one that merely meant the recognition of a symptom. One should also try to use names that meant something, in making a diagnosis. To do this, one must make a more thorough study of the patient, so as to get to the bottom of the case. Dr. McCrae believed that every physician could improve his work. While he considered postgraduate courses a help in this direction, he thought that every man could be his own postgraduate course. Doctors should all go back to the fundamentals more often than they did. They should read a good book on physiology at least once a year. Having discovered one's deficiencies, one should remedy them by determining that each day's work should be as well done as possible, and that the next day's work should be done even better.

Address of the Third Vice-President.—Dr. Henry B. Costill of Trenton, in this oration, considered some remarks made by the physicians of New Jersey on the selective draft, and some observations that he had made upon the work, as he had seen it, together with the conclusions that he had drawn therefrom. He stated that there were approximately two thousand New Jersey physicians in the service of the Government during the war, either in the army or in the navy, or on the draft boards. The membership of the society was 1721, and of these the number commissioned in the army was about 500; the number in the navy was about 48, and the number in the selective draft approximately 500, making more than one thousand of the seventeen hundred members that were giving their services to the Government. Dr. Costill remarked that the services of those who had been commissioned would

be recorded in the history of the war, but those who served in the selective draft had been accorded very scant recognition by the Government or the people. For this reason, he wished to review their work and the results they obtained. The cooperation of the advisory boards with the local boards was nearly always very complete. The boards were always ready with their quotas when the Government called for them, and there were very few complaints from the dependents. It required the finest kind of judgment to adjust these claims, and the selection of the men physically qualified for army service presented new problems to the civilian physicians. The fact that this work was done well was shown by the fact that New Jersey had the lowest percentage of rejections afterwards. At no time was a single war industry handicapped by a shortage of labor. An army of four million men was furnished in a little over a year, this constituting evidence of the value of the work performed by the draft boards. Dr. Costill drew the following conclusions from his observations: (1) The physical and mental defects found in one-third of the younger population pointed to errors in the educational system. Had proper care been exercised by parents during the pre-school life, scarcely any of these defects would have escaped detection. (2) The markedly better physical development of those with foreign parentage or foreign-born should arouse us to the danger of over-developing the minds of the children at the expense of their physique. (3) The growing number of heart lesions found among high-school and college graduates should lead to an inquiry as to how many heart strains are caused by allowing the boys to be pushed too rapidly into intensive training for various teams of football and other athletic sports. The speaker could not help feeling that the smoking of cigarettes might play an important part in the nervous heart, frequently found among registrants. (4) These observations would be incomplete if no attempt were made to compare these individuals as registrants with what they became after a few months of intensive training. Nothing could illustrate more clearly the desirability of compulsory physical training in our schools and colleges or a period of military training in the life of each child, male or female, than the improvement made in the physical condition of these young men within such a short period.

Election of Officers.—The following were elected as officers for the ensuing year: *President*, Dr. Gordon K. Dickinson of Jersey City; *First Vice-President*, Dr. Philander A. Harris of Paterson; *Second Vice-President*, Dr. Henry B. Costill of Trenton; *Third Vice-President*, Dr. James Hunter, Jr., of Westville; *Corresponding Secretary*, Dr. Harry A. Stout of Wenonah; *Recording Secretary*, Dr. William J. Chandler of South Orange; *Treasurer*, Dr. Archibald Mercer of Newark.

The next annual meeting will be held at Spring Lake in June, 1920.

AMERICAN SURGICAL ASSOCIATION.

Fortieth Annual Meeting, Held in Atlantic City, N. J., June 16, 17, and 18, 1919.

THE PRESIDENT, DR. LEWIS S. PILCHER OF BROOKLYN, IN THE CHAIR.

(*Concluded from page 303.*)

Second Day—Tuesday, June 17.

Thoracic Fistula and Chronic Empyema; a Non-deforming Operation for Their Cure.—Dr. HOWARD LILIENTHAL of New York stated that thoracoplastic collapsing operations for the cure of sinuses and pneumothorax following empyema were as a rule unjustifiable and unsurgical. Not only was there permanent thoracic asymmetry, but the affected lung was permanently deprived of much of its function. The method described by Dr. Lilienthal restored the lung quite or almost to its normal capacity while its danger was far less than that of the Schede, Estlander and Delorme operations. The operation consisted in the approach through a long seventh interspace incision beginning behind the costal angle and extending almost or quite to the cartilage. From one to four ribs were divided upward or sometimes downward at the posterior angle of the wound or very rarely upward at its anterior end in order to expose every recess of the cavity. A powerful automatic rib retractor was an absolute necessity in this operation. The lung which would be found bound down by adhesions was now liberated by incision through the confining membrane which might be removed if there was an easily found line of cleavage and which otherwise might be loosened by numerous intersecting incisions (Ransohoff). By intrapharyngeal insufflation the lung was then expanded and it should reach the chest walls. Fine bubbling on the surface was of no consequence, but whistling meant that a bronchus had been entered, and accident which should, if possible, be avoided. Drainage was secured through the original sinus enlarged for the purpose, the new surgical wound being closed by interrupted sutures of chromic catgut through the muscles but without pericostal sutures. The skin wound was approximated by silk or silkworm gut. The after treatment consisted in suitable dressings, Carrel-Dakin irrigations and strenuous blowing exercises. A simple bronchopleural fistule might be closed by means of bismuth oaste injected through the external wound. Beck's paste or 10 to 20 per cent. bismuth and vaseline might be used, the smaller percentages of bismuth being employed in cavities of larger size. Differential pressure of some sort in recent wounds with uninfected thorax where the mediastinum was not held rigid by exudate was a necessity.

The Delayed or Late Extraction of Intrathoracic Projectiles by the Method of Petit de la Villeon.—Dr. ROBERT G. LECONTE of Philadelphia in presenting this method said it depended upon the localization of the projectile with regard to its anatomical surroundings in contradistinction to its mathematical situation from surface markings. The projectile was removed by sight with forceps through a small buttonhole opening, with the employment of the *x*-rays and a fluoroscopic screen. The anatomical localization was discussed in seven different regions with regard to the dangerous and non-dangerous areas of the lung. The technique of the operation was described and the method of correlating the shadows of the tip of the forceps and the projectile by rotation of the operating table on its long axis. Three essentials for the successful practice of the method were, the acquiring of the radioscopic eye, the intuitive correlation of the two shadows made by the foreign body and the point of the forceps, and gentleness and dexterity of the hand. The underlying principle of success was dependent upon the fact that a closed forceps could be made to traverse a healthy lung without injuring vessels or bronchi. Danger from hemorrhage would come during extraction, when the blades of the forceps did not protect the surrounding tissues from the cutting edges of the projectile. Hemoptysis, pneumothorax, hemothorax, etc., were discussed and the after care of the patient given, with indication of danger zones from which projectiles should not be removed by this method, also a discussion of the removal of foreign bodies from the hilum of the lung. The statistics of 422 extractions gave a mortality of a little less than 1 per cent. The statistics of Dr. Robin's 92 extractions were discussed and the indications for operation given.

Dr. JOHN H. GIBBON of Philadelphia suggested that the discussion of the foregoing papers be opened by Dr. Antoine Depage since to a number of American surgeons working in France Dr. Tuffier had shown some very remarkable results following the treatment of old sinuses of the chest, which results Dr. Tuffier had attributed to the operation of Dr. Depage.

Dr. ANTOINE DEPAGE of La Panne, Belgium, said that in a very bad case of empyema which did not do well he had instituted the Carrel method, making a bacteriological count as described in his paper, when the wound promptly became sterile. It was then closed and the result was perfect. Subsequent cases had been treated in the same way and all gave very good results. Before suturing such cases Dr. Depage emphasized that the bacteriological count should be satisfactory and that there should be no secretion in the wound. Before suturing also, the edges of the wound should be freshened. In a large cavity the fluid would do no harm since it gradually was absorbed. It was

the opinion of Dr. Depage that the method would take the place of the operations of Schede, Estlander, and Delorme.

Dr. Alexis V. Moschowitz of New York regarded the essential elements in the treatment of empyema as the sterilization of the cavity, and the work which Nature would do subsequent to this. Out of the war he asserted that come two great big things—the fact of the winning of the war, and the Carrel-Dakin treatment.

Dr. Willy Meyer of New York in connection with the aid given by Nature in the healing of empyema recalled the case of a child of ten months of age in whom, because the use of the Carrel-Dakin was impracticable, formalin glycerin injections had been used. The sinus had unexpectedly closed, a pneumothorax was shown by the *x*-ray, but at the end of two weeks the child was entirely well. In a case of bismuth poisoning in which the bismuth oil had been injected into an old empyema to determine the extent of the cavity Dr. Meyer had been called upon to remove if possible the remainder of the oil. Reopening of the original resection of the rib being followed by a continuance of an irregular temperature the Carrel-Dakin had been instituted with the result that in 48 hours the man said he had never felt better in his life. The sinus had since become almost closed. The old chronic cases of empyema Dr. Meyer felt offered a good field for the use of differential pressure.

Dr. Albert J. Ochsner of Chicago referred to his report at the Philadelphia meeting of the Association of a series of cases such as described by Dr. Lilienthal in which he had used the mixed bismuth paste, following exactly the directions given by Beck. He had continued the use of the method and, without the figures at hand, was confident that many more than half of the cases had permanently recovered. The bismuth paste, however, he cautioned must be administered in strict accordance with the directions given.

Dr. Charles A. Powers of Denver referred to the work he had seen in France in the removal of foreign bodies from the thorax as described in the papers of Drs. Lilienthal and Crile, and regarded it as an illustration of marvelous surgical technique.

Dr. Joseph Ransohoff of Cincinnati referred to 80 cases of empyema under his care in the recent epidemic, in three of which the empyema had been double. Recovery had occurred in the whole number. In the treatment of empyema Dr. Ransohoff believed there was nothing so important as not to have an empyema. He believed that abscess of the lung occurred in about 6 per cent. of the acute empyemas. This draining in both directions created a connection between the pleural cavity, which was infected, and the base of the lung. In his cases this was not discovered until beginning the use of the Carrel-Dakin treatment, when some of the solution had been coughed up with rather unpleasant complications. He believed that while empyema cases might be closed with fluid present and remain closed for two or three years, yet so long as fluid was in the pleural cavity there was the possibility of the relighting up of the infection. He agreed fully with the statement that in some of the chronic cases the mere sterilization was not sufficient treatment; there was necessary a resection to free the lung and to allow it to expand.

Dr. Joseph A. Blake of New York believed with Dr. Ransohoff that the best treatment of chronic sinuses following empyema was their prevention. He was also of the opinion that in too many cases too much drainage was used at the primary operation, and that the drainage tubes and the treatment were responsible for the formation of sinuses. He regarded it as absolutely wrong to use the Carrel-Dakin treatment in the early stages of the case, instancing this by saying that in peritonitis, or in suppuration of the knee-joint, the use of the solution with the tubes and constant irrigation was unthinkable. It had been his unfortunate experience to see in France quite a large number of patients in whom the Carrel tube had been left for a long time, with a resultant sinus. The operation he observed must be done with judgment; in some cases much material was to be removed. The drainage tube should be left in for 36 hours. It was of importance that efficient drainage be instituted.

Dr. Lilienthal, in closing, said that the operation in properly selected cases was the operation of choice for the reasons already submitted in the paper. If the empyema patient could be cured without operation, so much the better. The operation was a purely surgical one, in which it was possible to see that the cavity was cleansed and to know that the chances for recovery were good. Nothing was easier than to close a thoracotomy wound, and those patients able to take care of what was left inside, even of a germ or two, would get well.

Dr. LeConte, in closing, said that in the irrigation of empyema he had been timid about using any considerable amount of fluid in the pleural cavity immediately after it had been opened, particularly in cases in which there was a bronchial fistule. His practice had been rather to sterilize the cavity with small, and gradually increasing amounts, according to the tolerance of the pleura in the individual case, of dichloramine-T 5 per cent. solution. This, he said, sterilized as rapidly as the Carrel-Dakin solution and the action of the diaphragm would pretty well coat the inside of the pleural cavity with the fluid. From these small amounts of dichloramine applied once or twice daily he had had as rapid healing, with less danger, as from bathing the surface with large amounts of solution.

Fractures of the Lower Third of the Femur.—Dr. Joseph Van de Velde of La Panne, Belgium, said that the compounding of these fractures during the war had considerably complicated the treatment. Open fractures by missiles were divided into fractures (1) With no comminution; (2) with slight comminution; (3) with much comminution. For each of those types, at La Panne, were used the following three methods of treatment: (1) Wiring; (2) Traction on the femoral condyles by ice-tongs, pins, or screws; (3) Depage's vertical suspension of the lower fragment combined with horizontal traction on the leg. The first type of fracture was the ideal one for wiring. If, after débridement, it was planned to make a primary suture of the wound, Dr. Depage's wiring method was used because the metallic tube which sustained the wire came out of the wound and afforded good drainage. For a secondary suture a bronze wire was used which was removed after a month before suturing the wound. In transverse fractures the ice-tong or vertical suspension was used and in a few cases Lane's plates, with good result. The use of screws in open contaminated fractures was not recommended. In the second type of fracture primary suture was dangerous and therefore a delayed primary or a secondary suture was made, and here the pin offered the best method. It was placed just above the condyle. When this was not possible it was to be passed through the anterior part of the condyle under the control of a fluoroscopic screen as was recommended by Fesson. The pin should not be left in place more than six weeks. For the third type of fracture in which was used the vertical suspension, combined with a horizontal traction on the leg, the vertical suspension was accomplished by passing a bronze wire through all the tissues of the anterior part of the thigh with a Reverdin needle. A finger introduced into the wound caught the wire and fixed it securely around the end of the lower fragment. Traction was made by a weight hanging above the bed of the patient. Shortening of the femur was prevented by traction. Some of the author's fractured femurs were kept for three months with this apparatus without pain or complication. The method had been used with excellent result also in cases of the lower third badly united and carrying a streptococci fistula. Here were recommended the subperiosteal resection of the ostitic callus and a vertical suspension of the lower fragment, and cases so treated had done wonderfully well.

Phases of War Surgery; Bone Transplants from the Tibia to the Lower Jaw for Loss of Substance.—Dr. Charles A. Powers of Denver presented a paper on this subject, illustrated by lantern slide pictures of the various stages which the transplants themselves underwent (*x*-ray findings) and also pictures of the patients. Dr. Powers had done eleven of these operations at the American Hospital at Neuilly in France. Of these eleven cases, eight, or 73 per cent., were fully successful; three, or 27 per cent., complete failures; while

one case, 9 per cent., was undetermined, but a probable success. However, dividing these eleven cases into classes by years, it was found that of the five cases done in 1916 two cases, 40 per cent., were successful, and three cases, 60 per cent., unsuccessful; while of the six cases operated upon in 1917 (after wider experience) five cases, or 83 per cent., were full successes (solid bony union, good mastication, excellent approximation of the dental arcades), and one case, 17 per cent., undetermined but probably successful. The results were, therefore, but moderately successful in 1916, but were fully successful in 1917. No operations were done by the author in 1918 owing to the changed conditions; the Militarized American Hospital No. 1 becoming an evacuation hospital for the American wounded. The author gave in detail his operative technique (with dentist's co-operation), which he had worked out. Dr. Powers stated that transplants to the lower jaw, in these battle casualties, had not found favor among the French surgeons and but moderate employment by British surgeons. He felt that while this series of eleven cases was not large, yet with the experience of the first year of work as a guide, the results in the second year had been most successful and satisfactory. Useless jaws had been returned to usefulness. Complete control over a very long period of time was absolutely necessary, and this obtained in the military service. Dr. Powers stated that the operation was a difficult one, through the proximity of the field to the mouth and nose, that it required the best of detail and best of assistance in every way. The slightest infection was practically always fatal to success. (The author's failures were due to infection.) He stated that the operation as worked out by him was not necessarily the best possible but that in view of his 1917 successes (five complete successes in six cases, the other a probable success) it was the best of which he knew at this time.

Cranioplasty; The Value of a Graft of Bone, Cartilage or Fascia in the Closure of Cranial Defects Caused by Wounds in War.—Dr. A. PRIMROSE of Toronto presented the results obtained in 42 operations performed on 38 patients in whom the majority of the defects had been in the frontal and parietal regions of the skull. In some of the cases a double gap had been present. Cartilage and bone grafts had been employed, all the former being autogenous; also the bone grafts except in one case in which a very large graft was transferred from the human cadavar. There was no operative mortality; infection of the wound occurred in five cases, two of which healed with a successful graft. In the following results only those cases were considered in which a firm closure was effected:

Cases completely relieved of distressing symptoms	19
Cases rendered worse by operation	2
Cases improved but not wholly relieved	8
Cases with no change in the symptoms	5
Total	34

The author gave the following conclusions: That it was possible to close a gap in the skull successfully by a graft of bone or cartilage; that the operation was attended by little danger to life; that the relief of symptoms directly dependent upon the existence of the gap was as a rule immediate and complete, such symptoms being headache, dizziness, the fear of injury, sense of insecurity, mental depression because of the presence of an ugly deformity. The value of the operation in Jacksonian epilepsy was less evident in the author's opinion, except in an amelioration of the attacks by removing cortical irritation.

Mr. W. HAY GROVES of England, while largely in accord with Dr. Van de Velde's principles of treatment, believed that the number of fractures with no comminution which required wiring was very small, and that the operation should be limited to those cases in which the widely separated fragments showed a real danger of intervention by the soft parts. Even in those cases the efficient extension apparatus available lessened the need of operation. In the treatment of the second type in Dr. Van de Velde's classification Mr. Groves believed that a pin directly through the lower end of the thigh would inevitably act as a seton, and that in a small definite proportion of cases, in his own experience 3 per cent. sepsis would occur. This danger would be entirely eliminated by tibial transfixion. Since the six weeks, beyond which Dr. Van de Velde said the ice-tongs or pins ought not to remain in place, would not see the case through, a measure of the greatest possible value in Mr. Groves' opinion was the transfixion of the tibia and the adjustment of a weight extension.

Dr. JOHN B. WALKER of New York said that only by the end results in fracture cases would the best means of treatment be determined. In this connection he expressed the hope that a certain amount of public opinion might be conveyed to the Office of the Surgeon General, urging that the records of war injuries might be rendered accessible for study.

Dr. JOSEPH A. BLAKE of New York regarded tibial traction comparatively safe from the standpoint of infection because in war injury the wounds extend farther down toward the knee, often interfering with a pin in the femur. In tibial traction, however, there was lost much control of the lower fragments, which was the important factor in the treatment of fractures. In every case where practicable to have the traction upon the femur it should be done.

SIR ARBUTHNOT LANE referred to the great development in the treatment of fractures of the lower jaw, and laid stress upon the lessened danger of sepsis in such fractures compared with that obtaining in fractures of the extremities.

Salvage of the Hand by Early Plastic Reconstruction.—Dr. JOHN B. ROBERTS of Philadelphia presented this paper, which was a plea for better personnel in the accident ward service of general hospitals in order that hands might not be unnecessarily mutilated by young graduates. These young doctors were very apt to sacrifice unnecessarily portions of fingers and hand which might be saved by skin grafting, applying pedicle graft from the abdomen or thigh, or removing only portions of crushed bone. The paper also called attention to the necessity for early treatment in Volkmann's contracture from anemic myositis and nerve pressure and for immediate tenosuture and nerve suture in accidental division of tendons and nerves. It also gave some information as to the way even portions of the forearm and arm might be used by the careful adaptation of artificial hands, or substitute for hands in the shape of hooks and springs.

Surgical Problems in the Reconstruction of Peripheral Nerve Injuries.—Dr. CHARLES H. FRAZIER of Philadelphia, after outlining the program of the Surgeon General's Office for the care and treatment of peripheral nerve injuries and the function of the Peripheral Nerve Commission, reviewed his experiences in the treatment of 550 cases under his direction at General Hospital No. 11. The proportion of cases in which operation which justifiable he placed at 30 per cent., although in some foreign clinics it had been only 16 per cent. As to the time of operation, he observed the three-month rule (not to operate until three months after the wound had healed), and was influenced by the fact that spontaneous recovery did not make itself manifest in the majority of cases until five to seven months after injury. Observing these two factors, he found that in many instances six months would elapse before the operation was undertaken. He laid down certain general principles in operative technique and then gave the indications for a neurolysis, which he had employed in only 30 per cent. of his cases. If one operated indiscriminately, the percentage of neurolysis might be increased to 50 or higher. The great problem of peripheral nerve surgery was the bridging of defects after resection. Discarding as unworthy of consideration the flap method, tubilization, lateral anastomosis and suture *à distance*, he discussed the application of other methods to which the surgeon must turn, notably, nerve-stretching, nerve transposition, the position of the limb, the nerve transplant, and an operation for which he had coined the word *implantation-suture*. The latter was applicable in the arm, where a healthy nerve might lie in juxtaposition to the injured, and differed from lateral anastomosis in that a portion of the healthy nerve was sacrificed. The essential factors to a successful suture were (1) the absence of undue tension, and (2) healthy fasciculi free from the inclusion of scar tissue in peripheral and central segments. With these regeneration would occur in spite of a clumsy

suture. Tendon transplantation, it was said, should be held in reserve for certain residual palsies, notably, those of the fingers in musculospiral palsies and those of the feet in external popliteal palsies (foot drop). Any discussion as to the superiority of method Dr. Frazier said must at this time be regarded as only of academic interest. The writing of the final chapter of the surgery of peripheral nerves in this country must be deferred until at least two years had elapsed since the operation. The Peripheral Nerve Commission, as a part of its function, would follow up all cases, and upon its findings would rest the final judgment as to the relative value of the different operative procedures.

Dr. Richard H. Harte of Philadelphia felt that to Dr. Frazier was due much appreciation for the time and care he had given in this rather non-spectacular type of surgery. The speaker had had occasion to refer to his care cases of nerve injury returned from the other side. He emphasized the importance of allowing the lapse of considerable time before operating upon nerve injuries and had very properly increased that period. There were scattered throughout the country many persons with peripheral injuries who would demand operation, and Dr. Harte believed it to be of the utmost importance that such work be done only by men of large experience in this particular department of surgery.

The Organization and Operation of an Evacuation Hospital.—Drs. Dean Lewis and Thomas J. Leary presented this paper, in which they said that an evacuation hospital should be an actively mobile unit, and, therefore, under tentage. All the organization should center about the operating department. A five hundred bed hospital could take care of the wounded of a division. A hospital of this character should carry 425 Gold Medal cots and 75 iron beds for the fracture cases. There should be in each hospital two *x*-ray machines and at least three, preferably four, *x*-ray men. Time should be conserved by having so many men rayed and waiting for operation that no operating tables would be empty. A surgeon, after finishing one operation, should be able to proceed immediately with the next. Perfect cooperation between the *x*-ray and operating department was necessary. Enough litter-bearers should be detailed to see that all tables were kept full. A linear setup of the tents of the operating department was the best, as it enabled the staff to keep track of the patients, and reduced the work of the personnel. The tents should be so arranged that the littering which was necessary was reduced to a minimum. The shock tent should be in close proximity to the receiving tent. The tents for nonevacuable and fracture cases should be near the operating tent and the evacuating platform.

Dr. J. M. T. Finney of Baltimore said that Dr. Lewis had set a standard which would be pretty difficult to follow, and that his organization had been a particularly efficient one. In such instances one had to deal with the personal equation, with the particular location assigned, with the transportation facilities, and last of all, but not least, with the enemy. All those factors must be taken into consideration and the efficient commanding officer would have an efficient organization. It should be borne in mind that from the beginning of the war until the armistice was signed the medical department had had at no time more than 50 per cent.—hardly that—of the medical personnel that it should have had. This meant that everybody was working at high tension, that most of the surgeons were doing the work of two or three men. This was true of the nurses and of the enlisted personnel. That the medical work of the war was so well done was due to the splendid spirit of self-denial, to team work on the part of the entire medical department, nurses and enlisted men; and he especially emphasized help of the latter because they had certainly done as good work as it was possible for any set of men to do.

Foreign Bodies in the Stomach.—Dr. Randolph Winslow of Baltimore, Md., in this paper said that foreign bodies were found in the stomachs of three classes of persons: (1) Those who swallowed objects accidentally; (2) the insane or otherwise unbalanced individuals, including those who swallowed articles with suicidal intent; (3) mountebanks or professional jugglers who ate glass and swallowed other dangerous objects as a means of livelihood. It was remarkable that so many sharp and pointed objects passed through the alimentary canal without producing serious results. Multiple objects were swallowed either by the insane or by mountebanks and practically all of these individuals came to operation sooner or later. Dr. Winslow reported a case in which he removed 1290 different objects from the stomach of an insane woman, which he believed to be the largest number of individual articles reported in the literature as having been successfully removed from the stomach of a living human being, though Vandivert and Mills reported the removal at autopsy of 1446 objects from the stomach of an insane mulatto woman. The foreign bodies removed by Dr. Winslow were as follows: Straight pins, hairpins, safety pins, pieces of bone hairpins, pieces of wire, buttons, iron screw staple, iron hook, wire nail, paper clamp, garter buckle, breast pin. Besides these the skiagraph showed pins and hairpins in the intestines previous to operation, and subsequently straight pins and two hairpins passed her anum. The woman made an uneventful recovery. Dr. Winslow said that while many single objects passed through the intestinal canal and were safely extruded, multiple foreign bodies usually lodged in the stomach and required to be removed by gastrotomy; that this operation was a comparatively safe one and the percentage of recoveries was very high, even when the foreign bodies had remained in the stomach a long time.

Dr. S. J. Mixter of Boston referred to a case seen in the operating room some time ago with a lump just above the umbilicus having the appearance of an abscess, in which incision revealed a quantity of yellowish pus which, interestingly enough, proved to be actinomycosis; the case was the first, he thought, recognized in Boston as human actinomycosis. In this abscess were two large fishbones.

Dr. Willy Meyer of New York said that some years before the time of the *x*-ray he had been called to operate for what had seemed to be a gastric lesion and had found a large knitting needle sticking out of the stomach. He also had seen a case in which a boy of four had swallowed an open safety-pin. The well known potato cure had been used with the removal of the safety-pin.

Third Day—Wednesday, June 18.

Operative Treatment of Peptic Ulcer.—Dr. John B. Deaver, Philadelphia, said that other things being equal excision of the ulcer or resection followed by gastroenterostomy was the procedure of choice. Other things, however, rarely were equal, and the powers, whichever they might be, which afflicted humankind with peptic ulcers did not always place them where they could without great difficulty be removed; or, as sometimes happened, in perforating ulcers the surgeon was spared the trouble of removing them. He could not entirely agree with Dr. Balfour's implication that spontaneous perforation if complete cured the patient. He had observed recurrence of perforation in two instances. Gastroenterostomy of itself was a curative measure for a time, but to insure a positive result the ulcer must be removed. It had been his experience that a gastroenterostomy properly made and properly placed, with a patulous, pylorus did not close. Resection plus gastroenterostomy presented the same advantages as the less complete one with the added benefit of a direct attack on the ulcer. Perforation of peptic ulcer in the past year occurred in about 5.2 per cent. of the author's cases. The proper time for medical treatment for the results of chronic indurated peptic ulcer was after and not before the operation—if treatment was then still needed. Carcinomatous degeneration of gastric ulcer was a menace which could not be ignored. Probably nowhere did the personal equation of the operator enter more than in the operative treatment of peptic ulcers. In ulcers distant to the pylorus with very little exudative induration simple excision might suffice. This applied also to saddle-back ulcers and those situated on the lesser curvature toward the cardia, for which circular resection was the indicated operation. From his experience on two occasions he was becoming convinced of the advantage of following circular resection with a gastroenterostomy. For per-

foration of a duodenal ulcer, he found it best, after closing the perforation, to plicate the duodenum and fortify the area by covering it over with the gastrocolic and the gastrohepatic omentum and complete the operation with a posterior gastroenterostomy. To January 1, 1919, the total number of perforations he had thus far treated amounted to 56 operations for perforated peptic ulcer with two deaths; one occurring twenty-two years ago and the other during the past year, making 54 consecutive operations with 100 per cent. recoveries.

Life Expectancy of Patients Following Operations for Gastric and Duodenal Ulcer.—Dr. DONALD C. BALFOUR of Rochester, Minn., observing that life expectancy was the major consideration with the patient, said that the records of the Mayo Clinic had been used by the Actuarial Society of America in an effort to determine the life expectancy of persons operated on for gastric and duodenal ulcer. In a study made of 2431 patients operated on between 1906 and 1915 and without regard to type of operation it was shown that the operative mortality from all causes in 545 cases of gastric ulcer was 4.5 per cent., an that in 1684 cases of duodenal ulcer the operative mortality from all causes was 2 per cent. The Association's investigations of the mortality in the years after operation showed that in 521 cases of gastric ulcer the patients were under observation on the average of 3.6 years, and that in that time 88 (17 per cent.) died from all causes. In 1651 cases of duodenal ulcer the patients were under observation on the average of 3.4 years, when 85 (approximately 5 per cent.) died from all causes. In gastric and duodenal ulcer of 91 patients under observation on the average of 3.8 years, 9 (10 per cent.) died. Mr. Arthur Hunter, who directed the work of the Actuarial Society, regarded as a high tribute to surgery the fact of the survival for three and a half years of 95 per cent. of patients operated on for duodenal ulcer. In gastric ulcer, also, a death rate in three and a half years of 17 per cent. of operated cases appeared to be low, and while the statement could not be proved Mr. Hunter's belief was that many years of life were saved through surgical treatment. The chief importance in the statistics, however, was the fact that the death rate of a group of persons following operation for gastric ulcer was four and one-third times as high as that of a group of the general population of similar age and sex. In the second year the death rate was three and one-fourth times as high, and in the later years it was still less. The death rate of a group of persons in the first two years following operation for duodenal ulcer was only that of a group of general population, and after the second year the mortality was actually less than in the general population group. The statistics illustrated strikingly that gastric ulcer was a much more serious condition than duodenal ulcer, not only from an operative standpoint, but from the after-results; also that the patient with a gastric ulcer showed, as a rule, much more evidence of impaired general health than did the patient with duodenal ulcer.

Cancer of the Stomach.—Dr. CHARLES H. MAYO of Rochester, Minn., said in this paper that the greatest number of cancers came in the area of highest acidity, the stomach. More than one-third of the cancers in men and more than one-fifth of the cancers in women appeared in this organ. Ninety-eight per cent. of intestinal cancers were in the colon, while cancer in the small intestine was rare, about 2 per cent. In taking a general survey of the various theories and reviewing the clinical evidence concerning the etiology of gastric cancer, it seemed that not one but several conditions were essential to its development. The change from the normal to the cancer cell was not great. In a general way it might be said that the nucleus was proportionately larger in the cancer cells than in the normal cells, and was ready for division with less than the average amount of cytoplasm surrounding it. When some cell exhausted its controlling granules in division and, reverting to primitive life, became parasitic, there might be the beginning of cancer, but only if other factors were present, such as acid condition, which undoubtedly stimulated cancer growth or greatly lowered alkalinity. It was reasonable to assume, concerning the normal division of a cell, that the brain directing its division came from the centrosome; possibly other granules might serve this purpose. From October 1, 1897, to January 1, 1919, 2,094 operations for cancer of the stomach were performed at the Mayo clinic. Seven hundred and thirty-six of these were resections, with a mortality of 13.7 per cent.; 746 were explorations, with a mortality of 2.9 per cent., and 612 were palliative operations, with a mortality of 11.1 per cent. For the last three years the anterior instead of the posterior Polya operation had been done in the clinic. Better after results seemed to be obtained by turning the bowel to the right, isoperistaltic, by closing the end of the stomach in toward the lesser curvature and protecting the closed portion by suturing the unopened bowel over it. Four hundred and twenty-seven patients were operated on during the three years previous to September, 1917. Those who died in the hospital and those not heard from numbered 121. Those who recovered from the operation and who had been heard from numbered 306; 115 (37.6 per cent.) of these showed three-year cures. Three hundred thirteen patients were operated on during more than five years before September 1, 1917. Those who died in the hospital and those not heard from numbered 79. Those who recovered from the operation and who had been heard from number 234; 59 (25 per cent.) of these showed five-year cures. This was a most satisfactory showing for the surgical relief of an otherwise hopeless condition which was attended by much suffering.

Dr. ARTHUR D. BEVAN of Chicago said he had been fortunate in having been associated with a colleague with a very large service in diseases of the stomach, and he had become convinced that the great majority of gastric and duodenal ulcer can be cured medically, and can be kept cured under proper after treatment. With the opportunity of studying a large series of cases, surprising results of surgical management would be seen in recurrences after gastroenterostomy for ulcer. He believed, however, that most medical men did push the matter of medical therapy too far. An ulcer persisting after proper medical treatment was a surgical matter. The treatment of cancer of the stomach was as definitely surgical as was carcinoma of the breast. The science of diagnosis as applied to cancer of the stomach must remain largely in the hands of the internists, and that they were becoming very expert in the early diagnosis of cancer was a matter of great value. Within the last month he has resected three stomachs in which there was very early carcinoma. Carcinoma of the stomach was one of the most curable carcinomas in the body if it were early recognized.

Dr. FRANK E. BUNTS of Cleveland stated that the curative result of a gastroenterostomy was not to be measured by the immediate result of the operation, but such cases demanded the most careful attention following the operation that could be given by the best medical men.

Abscess of Rectus Muscle Following Influenza.—Dr. HOMER GAGE of Worcester, Mass., said in this paper that, next to empyema, the principal complication of surgical interest in the influenza epidemic at Camp Devens was a group of localized abscesses, most often periarticular and intramuscular, not involving the joints or any of the internal organs usually involved in metastatic processes. Of especial interest in this group were three cases of abscess of the rectus muscle, to which had been added a fourth case observed at the Infants' Hospital in Boston by Dr. W. E. Ladd and, with his kind permission, included here. They were first observed about a month after the onset of the pneumonia—two had no other complication; the third had empyema and an abscess in the chest wall. Culturally all showed pneumococci—two type I, one untyped. All recovered promptly after incision and drainage. In the autopsy reports made by Dr. S. Burt Wolbach, nine cases presented clearly defined Zenker degeneration of the recti muscles with rupture of the muscle fibers and intramuscular hemorrhage. To a lesser degree the same process was observed in other muscles of the abdomen and in muscles of the chest. It seemed quite evident that these abscesses represented infected muscle hematomata and that the infection was blood borne. They presented themselves late in the disease, were not accompanied by manifestations of general sepsis, and were not readily diagnosed because unsuspected. Their presence in the tissues about the

joints and in the abdominal muscles, and their absence in the joints themselves and in the abdominal viscera, suggested the possibility of a selective action on the part of the infecting agent.

Traumatic Facial Diplegia.—Dr. JOSEPH RANSOHOFF, Cincinnati, presented the history of a case of complete bilateral facial paralysis following a street car accident. The *x*-ray showed a fracture through the left temporal bone. The paralysis of the right side followed two days after that of the left. No other cranial nerves were involved. The taste function of the anterior two-thirds of the tongue was completely lost. Return of muscular power was first noticed on the right side. Both sides were completely restored. The lesion was doubtless in the path of the nerve between the geniculate ganglion and the point where the chorda tympani leaves the nerve trunk. The speedy recovery indicated a hemorrhage as causative agent. The author believed that only four other cases of traumatic facial diplegia had been recorded, since at least two of the earlier cases were not double paralysis of the facial, but of the facial and acoustic of the same side.

The Results of Splenectomy in the Anemias.—Dr. WILLIAM J. MAYO, Rochester, Minn., in this paper, said that splenectomy as a curative agent had been given a fair trial in three types of the anemias—splenic anemia, pernicious anemia, and hemolytic icterus—and its successes and failures could be reasonably shown by the data at hand. *Splenic Anemia:* While splenic anemia was a clinical entity, it could not be said to have a definite pathological existence. It might be defined as a fibrotic splenomegalia with marked endophlebitis causing a secondary type of anemia which was progressive but not constant until the later stages. A few clinicians regarded all splenic anemias as syphilitic in origin, but the writer's experience did not bear out this theory. A much better idea of splenic anemia would be obtained if the pathological condition of the spleen and its effect on the blood were made the criteria, and all cases of known causation as well as those of unknown causation were classified as splenic anemia. Banti's disease was merely a late phase of some cases of splenic anemia. Of sixty-one patients with splenic anemia from whom the spleen was removed seven (11.7 per cent.) died. *Pernicious Anemia:* The etiology of pernicious anemia was unknown, the early symptoms were indefinite, and by the time the diagnosis could be made the patient could not be cured. The disease might be described as a progressive degeneration of the red blood in which there was a permanent loss of blast cells or mother cells of the erythrocytes. If it might be asserted that the spleen exhibited definite pathologic changes or that in cases of pernicious anemia in which the hemolysis was most marked patients had a greatly enlarged spleen, a direct connection between the spleen and the disease would be established. Unfortunately, however, experience did not support this hypothesis, and the size of the spleen did not seem to bear definite relationship to the severity of the disease. Splenectomy in pernicious anemia did not appear to be based on sound reasoning and there seemed to be little foundation for the belief that the procedure would cure pernicious anemia, although splenectomy was a means of marked palliation. Fifty patients with pernicious anemia were splenectomized, with three deaths (6 per cent.). *Hemolytic Icterus:* Hemolytic icterus had not been classified with the anemias, but the peculiar splenic activity resulted in an anemia which was the cause of death. As in splenic and pernicious anemias, the etiology of hemolytic icterus was unknown. The well-developed case of hemolytic icterus stood out with a vividness unequaled in splenic anemia and in pernicious anemia. The characteristic features were an enlarged spleen, chronic jaundice with exacerbations, normally bile-colored feces, and absence of bile in the urine. The enormous destruction of red corpuscles in the spleen inundated the liver with blood pigments and rendered the bile thick. The viscid bile in hemolytic icterus tended to form gallstones. Sixty per cent. of all the patients with hemolytic icterus operated on had associated gallstones and all the possibilities of biliary duct infection. The triumph of splenectomy was the cure of hemolytic icterus. The only patient lost of the twenty-seven splenectomized for hemolytic icterus was one operated on during an acute exacerbation.

A Case in Which for Over Thirty-five Years a Woman Defecated and Urinated and for Eleven Years Menstruated by the Rectum.—Dr. W. W. KEEN of Philadelphia, in this paper, said that the case designated by this title was worthy of a final record as an evidence of the possibilities of surgery and especially of the conclusive evidence afforded that the rectum could be utilized as a common cloaca for the urine and the menstrual flow as well as for the feces for an indefinite period. The case was one of extensive and incurable vesicovaginal and rectovaginal fistulæ caused by sloughing as a complication of typhoid fever. Ultimately Dr. Keen entirely closed the vaginal outlet. He had first reported the case in his Toner lecture in 1876. Only one similar case had ever been published. This was by Baker Brown in 1864. Reuben Peterson had assembled (*Surgery, Gynecology and Obstetrics*, 1917) thirty-eight other similar cases in addition to two of his own. In 1851 Maisonneuve had performed this operation for the first time, but his was not published until 1889. Rose had operated on three cases, in 1872, 1883, and 1886; one case was published in 1878, the other two in 1903. Dr. Keen's case was the only one in which the condition was caused by typhoid fever. In thirty-three cases in which the cause was stated, twenty-five resulted from childbirth and four from operations for cancer. Closure of the vagina was successful, except at the internal end of the remnant of the urethra. After several minor but unsuccessful operations done here, he excised this small remnant with entirely successful results. Fistulæ in the cicatrix broke out at intervals of two, nineteen, and eight years, but were easily remedied. Thirteen years after the vaginal closure there was escape of urine. Digital examination by the rectum showed contraction of the rectovaginal fistula and the presence of a calculus in the vagina. The calculus was crushed by curved hemostatic forceps introduced through the rectum. At death the patient, at the age of seventy-three, had remained dry and well, with the exceptions noted, for thirty-five years and five months after the closure of the vaginal outlet.

REPORT OF A SERIES OF PNEUMONIA CASES COMPLICATED WITH EMPHYSEMA.

BY LIEUT. D. M. MYQUIST, M. C., U. S. A., and LIEUT. V. A. ROSS, M. C., U. S. A.

DURING an epidemic of influenza, followed by bronchopneumonia, at Camp Hospital No. 12, American E. F., a unique and almost unheard of complication of subcutaneous emphysema of face, neck, and chest wall, and in a few cases of practically the entire body, was noted in thirteen cases, and it was our unusual opportunity, through the kindness of Major Frank W. Snow, commanding officer, to be assigned to study them from a clinical and etiological standpoint.

The following is a history of the salient findings of cases that presented themselves:

CASE I—Private K, Battery "A," 3rd Field Artillery, admitted to Camp Hospital, September 14, 1918, had become ill the day before, with generalized muscular pain, dull frontal headache, cough and greenish-yellow, mucopurulent expectoration, and chilly sensations. Physical findings were negative outside of slight injection of pharynx. Diagnosis—Influenza.

On the evening of September 20 there was an elevation of temperature, pulse, and respiration. The following morning physical examination revealed two small areas in the lower left posterior lobe where percussion elicited dullness; auscultation over these areas gave bronchial breathing. Also coarse râles were heard over the entir left lung and crepitant râles were present at the base of the right lower posterior lobe. Diagnosis—Bronchopneumonia.

There was no marked changed in the physical findings of the patient until September 23, when the whole left lower lobe was dull to percussion (coalescing of bronchopneumonia areas), and there was another dull area about three centimeters in diameter in the right lower posterior lobe. At this time there appeared a symmetrical elevation of the skin in the supraclavicular fossae. Further inspection of the body showed the condition to be restricted to the above-named area. On palpation the characteristic crepitation of gas in the subcutaneous tissue was present. The patient complained of no pain or tenderness over the involved area; nor were there present any signs or symptoms of a local inflammation. At this time there was no apparent change in the condition of the patient. The process spread symmetrically until it reached its maximum involvement September 28, at which time the subcutaneous gas extended from about nine centimeters below Poupart's ligament into the scrotum, up into the subcutaneous tissue of the abdomen, back, thorax, upper extremities, to the margin of the finger nails (the palms of the hands being exempt), up into the neck and face, reaching the hair line, where it stopped. Now pain and tenderness on palpation were elicited, but the distention was great enough to cause pain by itself. At this time the pulmonary condition was clearing.

The subcutaneous gas now progressively decreased and by September 30 all pain and tenderness of the skin was absent. The patient's pulmonary condition gradually cleared. Convalescence was uneventful except for a pericarditis and fairly definite signs of endocarditis which developed October 8.

At the present time, November 11, the lungs are negative; heart rapid but otherwise normal, and the subcutaneous gas has all disappeared except a small amount in the scrotum and in the region of the symphysis pubis.

Laboratory Findings: (*A*) Blood Culture: No. 1, Negative. No. 2, Negative. (*B*) Nasopharyngeal Swab: Gram negative bacilli. Gram positive diplococci. (*C*) Sputum: Gram positive diplococci, pneumococci type II (Avery method). Gram positive chains of cocci. Gram positive clusters of cocci.

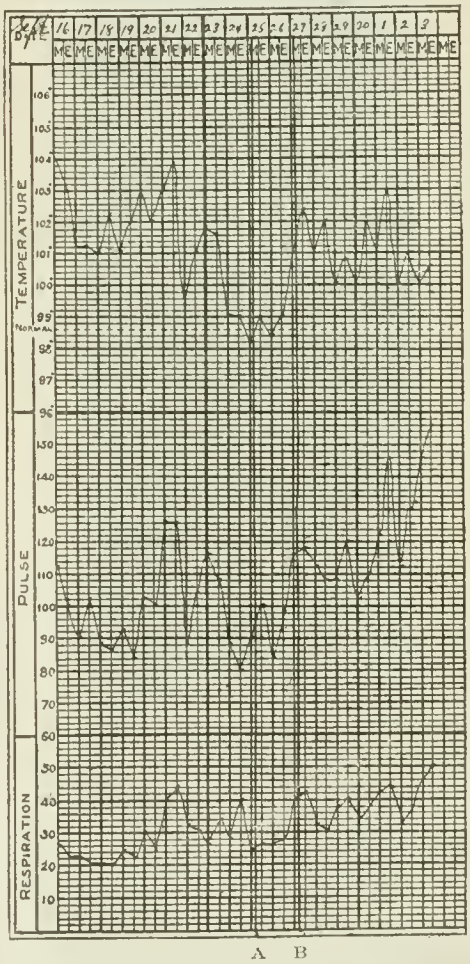

CHART 1.—Case II. A, time of onset of subcutaneous emphysema; B, time of maximum extent of the emphysema.

CASE II.—Private F, Battery "B," 78th Field Artillery, admitted to Camp Hospital September 16, complaining of rigor, generalized muscular pain, a productive cough, greenish-yellow expectoration, throbbing frontal headache and prostration. Physical examination revealed nothing except an injected pharynx. Diagnosis—Influenza.

On September 20 physical examination of patient showed an area of dullness and tubular breathing over a small area in the left lower posterior lobe. Respiration and pulse are increased as chart below indicates. Diagnosis—Bronchopneumonia.

September 23, patient became slightly cyanotic; there was dullness to percussion over whole right and left lower lobes, giving physical signs of lobar pneumonia. In the evening of September 25, the presence of subcutaneous gas was detected by palpation over the left pectoralis major muscle. There were no signs or symptoms of local inflammation present. Pulse, respiration, cyanosis and general condition was not altered from previous day. From the initial involved area the subcutaneous gas spread up into the neck to margin of jaw on both sides and down over anterior thorax to costal margin on both sides—at which time, September 27, the process reached its maximum involvement. Physical examination at the time revealed

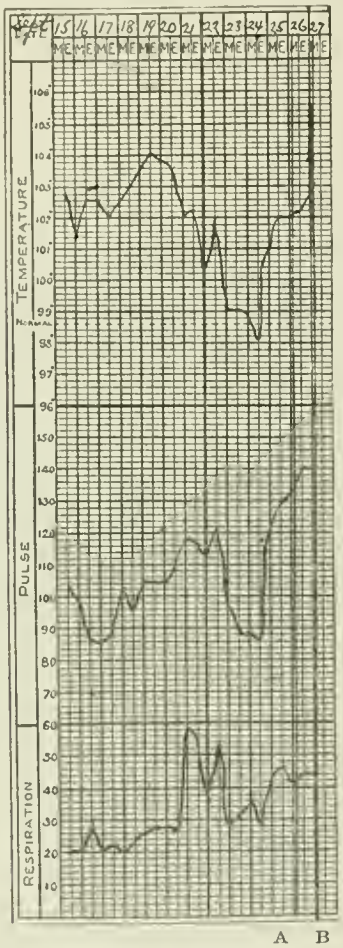

Chart 2.—Case III. A, time of onset of subcutaneous emphysema; B, time of maximum extent of emphysema.

no change from the previous found conditions except that the liver was palpable one finger breadth below the costal margin.

On September 30, there appeared over the anterior surface of the thorax, numerous round, pin-head sized, elevated vesicles, having a non-erythematous base, which upon rupturing exuded a clear fluid. From this time on cyanosis became more marked, respiration increased, pulse became very rapid and of small volume, which condition progressively increased until death, October 3. The subcutaneous gas after reaching its maximum involvement remained stationary until the end.

Autopsy showed the following points of interest: There was gas present, besides where clinically mentioned, in the mediastinal tissue of the lungs. The lungs showed the usual findings of a coalescing of bronchopneumonia areas. The bronchi and bronchioles were filled with a purulent exudate. The cut surfaces of the consolidated lungs revealed numerous miliary abscesses. There was evidence of rupture of the lung present, but no air could be forced out.

Laboratory Findings Prior to Death: (*A*) Blood Culture: No. 1, Negative; No. 2, Gram positive bacilli. (*B*) Nasopharyngeal Smears: Gram positive chains of cocci; Gram negative diplococci; Gram positive diplococci. (*C*) Sputum: Gram positive diplococci, pneumococci, Type I (Avery method); Gram positive clusters of cocci; Gram negative bacilli.

Laboratory Findings After Death: (*A*) Cultures from Heart Blood: Gram positive chains of cocci; Gram positive bacilli. (*B*) Cultures from the Pericardial Fluid: Gram positive chains of cocci. (*C*) Cultures from Right Pleural Sac: Gram positive chains of cocci. (*D*) Cultures from Left Lower Lobe of Lung: Gram positive diplococci; Gram positive chains of cocci; Gram negative bacilli, few. (*E*) Cultures from Emphysematous Areas: (1) Left pectoralis major muscle: Gram positive cocci, few. (2) Mediastinal Tissue: Large gram positive bacilli, few. (3) Right Parabronchial Gland: Short chains of gram positive cocci. (*F*) Smears and Cultures from the Trachea and Bronchi: Gram positive diplococci; Gram negative bacilli; Gram positive cocci in chains and in clusters. (*G*) Cultures from Left Frontal Sinus: Gram negative bacilli; Gram positive cocci.

Case III.—Private L., Battery "C," 3rd Field Artillery, admitted to Camp Hospital, September 14, 1918, complaining of rigor, generalized muscular pain, throbbing tempero frontal headache, a productive cough, expectorating a yellow, tenacious sputum. Physical examination was negative. Diagnosis—Influenza.

The patient's symtoms increased in severity but not until September 20 were there any physical findings present. In the left posterior lower lobe there was a small area of impaired resonance with increase of breath sounds. Diagnosis—Bronchopneumonia.

The area involved in the left lower lobe increased in size until by September 22 the whole lobe gave dullness to percussion with tubular breathing, as did also a small area in the right posterior lobe. At this time cyanosis was slight. By September 24 the whole right lobe showed consolidation. Cyanosis was more marked. A generalized jaundice was now present.

In the morning of September 25 there appeared a symmetrical distention of the skin in the supraclavicular fossae; and upon palpation over this area, distinct crepitation was elicited. No signs or symptoms of local inflammation were present. The process spread, extending from the margins of the jaw on both sides and to the fifth rib on both sides by September 27, at which time the patient died.

Autopsy showed the usual findings of bronchopneumonia with small miliary abscesses throughout involved area. Capillary hemorrhages were present in the lungs. The lung tissue involved was broken down, almost gangrenous. Gas was present, besides where clinically mentioned in the mediastinal tissue and pericardial fat. No laboratory work was done.

Case IV.—Private S., Headquarters Company, 3rd Field Artillery, admitted September 16, 1918, complained of generalized muscular pain, throbbing frontal headache and a non-productive cough. Physical examination was negative except for a few subcrepitant râles in left lower posterior lobe. Diagnosis—Influenza. September 21, physical examination revealed a small area of impaired resonance with increased breath sounds in the left posterior lower lobe. Diagnosis—Bronchopneumonia. September 22, dullness with tubular breathing was present over the whole left lower posterior lobe and increased breath sounds over right posterior lower lobe with a pleural rub.

On September 26 there was first noticed a distention of the skin in the left supraclavicular fossa. Palpation over above area gave characteristc crepitation of gas in the subcutaneous tissue. There were no signs or symptoms of local inflammation present. Lung involvement was same as previously described. On September 27 the subcutaneous gas reached its maximum involvement, extending from the margin of the jaw to costal margin on both sides. The liver was now one and half finger breadths below the costal region. Spleen was not palpable. Signs of a small amount of

fluid were present in the right lower chest. The subcutaneous gas remained stationary, but the symptoms increased in severity until patient's death October 5.

Autopsy revealed the following salient points: There was present a small amount of pus in right pleural cavity. The right and left lower lobes showed characteristic findings of a coalescing of bronchopneumonia patches and the cut surfaces of these lobes were studded with small miliary abscesses. Gas was present, besides where clinically mentioned in the mediastinal tissue and in the interstitial tissue of the lungs.

Laboratory Findings Prior to Death: (*A*) Blood Cultures: No. 1, Negative; No. 2, Negative. (*B*) Nasopharyngeal Swabs: Gram positive diplococci, pneumococci Type III (Mouse); Gram positive chains of cocci; Gram negative cocci. (*C*) Sputum: Gram positive diplococci; Gram negative diplococci; Gram positive chains of cocci.

Laboratory Findings After Death: (*A*) Cultures from Heart Blood: Gram positive diplococci. (*B*) Cultures from Pericardial Fluid: Gram positive chains of cocci. (*C*) Cultures from Trachea: Gram negative bacilli; Gram positive diplococci; Gram positive chains of cocci; Gram positive bacilli, large. (*D*) Cultures from Right Bronchus: Gram negative bacilli; Gram positive diplococci; Gram positive chains of cocci. (*E*) Cultures from Right Pleural Pus: Gram positive chains of cocci. (*F*) Cultures from Right Lung: Gram positive chains of cocci; Gram negative bacilli, few. (*G*) Culture from Left Pectoralis Major Muscle: Gram positive bacilli, large.

NOTE.—The bacilli isolated from the pectoralis major muscle had the same morphological characteristics as those found in Case II.

CASE V.—Private A., 6th Trench Motor Battery, admitted to Camp Hospital September 16, with diagnosis of influenza, developing a patch of bronchopneumonia in left, lower lobe September 19. By September 25 there was complete consolidation of left, lower lobe, and also a small consolidated area in right lower, posterior lobe.

Distention of the skin in the supraclavicular fossæ was first noticed September 26. Palpation over involved area gave crepitation. By September 27 the subcutaneous gas had spread up to the margin of jaw and down to costal margin on both sides. The liver was now one and half finger breadths below costal margin. The subcutaneous gas progressively disappeared and by October 3 no trace of it could be found. At no time was there any sign of symptoms of a local inflammatory process present. Patient well.

Laboratory Report: (*A*) Blood Culture: No. 1, Negative; No. 2, Negative; No. 3, Negative. (*B*) Nasopharyngeal Swabs: Gram negative bacilli, few; Gram positive diplococci; Gram negative diplococci. (*C*) Sputum: Gram positive chains of cocci; Gram positive diplococci, pneumococci, Type IV (Avery); Gram positive clusters of cocci.

CASE VI.—Private H., Battery B, 11th Field Artillery, admitted September 18, with diagnosis of influenza, developing in the left, lower, posterior lobe a patch of bronchopneumonia on September 24. This involved area of the lung spread so that by September 27 the whole left lower lobe and right lower lobe were consolidated. On the same date there appeared a symmetrical distention of the skin over the first intercostal spaces which progressively spread, extending from the hair line of the head to Poupart's ligament on both sides, by September 29, when the patient died. Prior to death, palpation over involved area gave the characteristic crepitation of gas beneath the skin, and there were no signs or symptoms of local inflammation.

Autopsy showed the following points of interest: Both lower lobes revealed a purulent bronchopneumonia with small miliary abscesses throughout and with evidence of small capillary hemorrhages. There were scars on the surface of the lung indicating rupture. Gas was present, besides where clinically mentioned, in the mediastinal tissue and pericardial fat.

Laboratory Findings Prior to Death: (*A*) Blood Culture: Gram positive bacilli. (*B*) Nasopharyngeal Swab: Gram positive diplococci; Gram positive chains of cocci: Gram negative bacilli; Gram negative diplococci. (*C*) Sputum: Gram positive diplococci, pneumococci, Type III; Gram positive chains of cocci.

Laboratory Findings Following Death: (*A*) Cultures from Heart Blood: Gram positive diplococci; Gram positive bacilli. (*B*) Cultures from Left Pleural Sac: Gram positive diplococci. (*C*) Cultures from Pus in Left Bronchus: Gram positive diplococci; Gram negative bacilli. (*D*) Cultures from Right Lower Lobe of Lung: Gram positive diplococci; Gram positive chains of cocci. (*E*) Cultures from Left Pectoralis Major Muscle: Gram positive bacilli, large.

CASE VII.—Private K., Battery B, 3rd Field Artillery, admitted to Camp Hospital, September 18, with

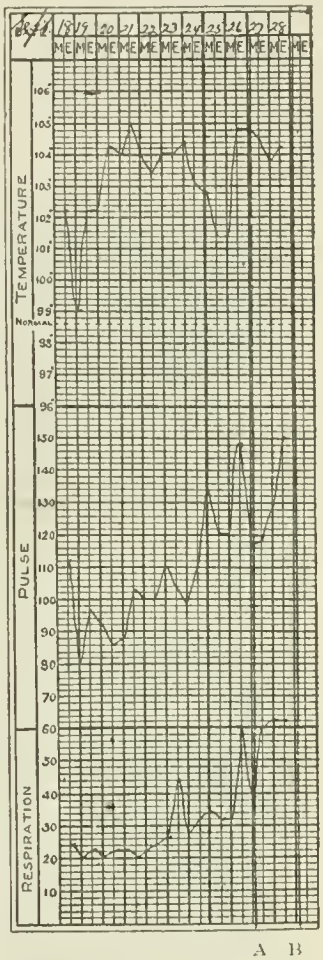

CHART 3.—Case VI. A, time of onset of subcutaneous emphysema; B, time of maximum extent of the emphysema.

diagnosis of influenza. On September 23, patient developed lobar pneumonia in right and left lower lobes. September 28, right otitis media developed with indications of a mastoid involvement. Then on September 29, a distention of the skin in the supraclavicular fossae and neck was noticed; palpation over this area gave crepitation characteristic of subcutaneous gas. The area involved spread progressively, extending from the margin of the jaw to the fifth rib on both sides by October 1, when process remained stationary until death on October 4. At no time was there evidence of a local inflammatory process.

Autopsy: Lungs were covered with a gelatinous exudate and cut surfaces of the consolidated lower lobes show a few small miliary abscesses and pus exuding from the bronchioles. Small hemorrhages were present in the lung tissue. No evidence of rupture of the lung area was present. Gas was present, besides where clinically mentioned, in the mediastinal tissue, in the pericardial fat, and in the chest wall.

Laboratory Findings Prior to Death: (*A*) Blood Cultures: Gram positive chains of cocci. (*B*) Nasopharyngeal Swab: Gram positive bacilli, few; Gram negative bacilli; Gram positive diplococci. (*C*) Sputum: Gram positive diplococci, pneumococci, Type II (Avery); Gram positive chains of hemolytic streptococci; Gram positive clusters of cocci.

Laboratory Findings Following Death: (*A*) Cultures from Heart Blood: Gram positive diplococci, pneumococci, Type II (Avery). (*B*) Cultures from Trachea: Gram negative bacilli; Gram positive diplococci; Gram positive chains of cocci. (*C*) Culture from Left Lower Lobe: Gram positive chains of cocci; Gram negative bacilli, few; Gram positive diplococci. (*D*) Culture from Exudate on Right Lung: Gram positive chains of cocci, hemolytic streptococci. (*E*) Culture from Small Abscesses in Right Lower Lobe: Gram positive diplococci; Gram positive chains of cocci; Gram positive clusters of cocci, few. (*F*) Cultures from Left Pectoralis Major Muscle: Gram negative bacilli. (*G*) Culture from Spleen: Gram negative chains of cocci. (*H*) Cultures from Right Mastoid Cells: Gram negative bacilli; Gram positive chains of cocci; Gram positive clusters of cocci. (*I*) Cultures from Intestinal Contents: Small gram negative motile bacilli; Gram negative cocci; Gram positive bacilli, large, non-motile.

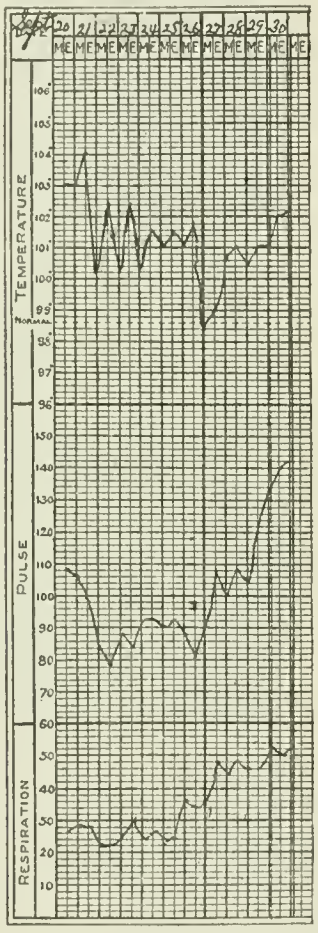

CHART 4.—Case VIII. A, time of onset of subcutaneous emphysema; B, time of maximum extent of the emphysema.

CASE VIII.—Private V., Battery F, 78th Field Artillery, admitted to Camp Hospital September 20, with diagnosis of influenza, developing varicella September 23 and bronchopneumonia on September 27. On September 30, a distention of the skin appeared in the supraclavicular fossæ. Palpation over the above area gave crepitation. The process spread, extending from the margin of the jaw to the fifth rib on both sides, at the time of death, October 1. No signs or symptoms of local inflammation were present.

Autopsy: Left pleural sac contained a small amount of exudate. Bronchopneumonia findings in both lower lobes with miliary abscesses throughout the involved areas. Gas was present, besides where clinically mentioned, in the mediastinal tissue and pericardial fat.

Laboratory Findings Following Death: (*A*) Cultures from Heart Blood: Gram positive bacilli (subtilis group, contamination); Gram positive diplococci. (*B*) Cultures from Right Lung: Gram positive diplococci, pneumococci, Type II (Avery); Gram positive chains of cocci; Gram negative bacilli. (*C*) Cultures from Left Pleural Exudate: Gram positive cocci hemolytic streptococci. (*D*) Culture from Bronchus: Gram positive diplococci; Gram positive chains of cocci. (*E*) Culture from Left Pectoralis Major Muscle: Negative. (*F*) Culture from Right Pectoralis Major Muscle: Gram positive cocci. (*G*) Culture from Mediastinal Tissue: Gram positive cocci. (*H*) Culture from Pericardial Fluid: Negative.

CASE IX.—Private C., Battery B, 318th Field Artillery, admitted to Camp Hospital, October 7, with diagnosis of bronchopneumonia. Patient had influenza September 23, in neighboring infirmary. On October 5 a distention of the skin in the supraclavicular fossæ appeared. Palpation over the above area gave crepitation characteristic of gas in the subcutaneous tissue. The involved area spread, extending from the margin of the jaw to the costal region on both sides by October 7, where it remained stationary until death, October 11. At no time were there any signs or symptoms of a local inflammation present.

Autopsy: Both right and left lower lobes showed patches of bronchopneumonia, and cut surfaces revealed a number of miliary abscesses throughout involved areas. The bronchioles and bronchi were filled with a greenish-yellow pus. Gas was present, besides where clinically mentioned, in the mediastinal tissue and in the interstitial tissue of the lungs.

Laboratory Findings Prior to Death: (*A*) Blood Culture: No. 1, negative; No. 2, gram positive diplococci, pneumococci, Type II (Avery). No other laboratory work was done.

CASE X.—Private B., Headquarters Company, 20th Forestry Engineers, admitted to Camp Hospital, September 30, with diagnosis of influenza. On October 4 bronchopneumonia developed in the right lower posterior lobe, and October 6 a patch of bronchopneumonia developed in the left lower posterior lobe. Patient's symptoms progressively became worse. On October 10 a pericarditis developed and also at this time there appeared a distention of the skin in the supraclavicular fossæ and in the first and second intercostal spaces of both sides. The characteristic crepitation of gas in the subcutaneous tissue was elicited by palpation. This process spread from the margin of the jaw to the costal margin on both sides by October 11, at time of death. At no time were there present any signs or symptoms of a local inflammation.

Autopsy: Right and left lower lobes of the lungs were solid, being nodular in consistency. The cut surfaces of these lungs showed numerous miliary abscesses especially well marked in the region of the bronchi. The bronchioles and bronchi coming from these lobes were full of tenacious yellow pus. The two upper lobes showed consolidated areas about the bronchi. The cut surfaces of these nodules revealed also numerous miliary abscesses. The pericardial fluid was increased. Gas was present, besides where clinically mentioned, in the mediastinal tissue, in the pleural sacks and in the pericardial fat.

Laboratory Findings Prior to Death: (*A*) Blood Culture: No. 1, gram positive diplococci, Type II (Avery). (*B*) Nasopharyngeal Swabs: Gram positive diplococci; gram positive chains of cocci; gram negative bacilli.

Laboratory Findings Following Death: (*A*) Culture from Heart Blood: Gram positive diplococci; gram negative bacilli. (*B*) Cultures from Pericardial Fluid: Gram positive diplococci. (*C*) Culture from Trachea: Gram negative bacilli, many; gram positive diplococci; gram negative diplococci, many. (*D*) Cultures from Right Lower Lobe of Lung: Gram positive bacilli; gram negative bacilli; gram positive diplococci; gram positive chains of cocci. (*E*) Cultures from Right and Left Pectoralis Major Muscles: Gram negative bacilli. (*F*) Culture from Mediastinal Lymph Node: Gram positive chains of cocci.

Note.—The gram positive diplococci from the pericardial fluid proved to be Type III pneumococci (Avery). The gram negative bacilli from the heart blood and pectoralis major muscle belonged to the Proteus group.

Case XI.—Private F., Battery F, 124th Field Artillery, admitted August 15, with diagnosis of influenza. On August 19 bronchopneumonia developed in the right lower lobe. August 22 the whole right lung gave signs of consolidation. October 14 a diagnosis of empyema on right side was made. On October 15 a resection of the right fifth rib in axillary line, with drainage, was done. October 16 crepitation characteristic of gas in the subcutaneous tissue was detected by palpation. This area extended above and lateral to the incision for a radius of about eight centimeters. The involved area did not spread, but gradually decreased until gas was entirely gone by October 20. Again there were no signs or symptoms of local inflammation. Termination—Convalescence.

Laboratory Findings: (*A*) Blood Culture Taken August 22: Negative. (*B*) Sputum Taken August 22: Passed through mouth, failed to give pneumococci or streptococci. (*C*) Culture from Pus in Pleural Sac: Pneumococci.

Case II.—Private P., Battery A, 78th Field Artillery, admitted September 30, with diagnosis of influenza. On October 2 a patch of bronchopneumonia developed in the right lower posterior lobe, and on October 3 there was dullness from the right inferior angle of the scapula to base. On October 15 empyema in the right midaxillary line was diagnosed. A resection of the fifth rib with drainage was done October 16. On October 17, the day following the operation, there was a distention of the skin above and lateral to the incision. Palpation over the involved area gave crepitation characteristic of gas in the subcutaneous tissue. By October 18 the area involved had extended above the incision to the clavicle, over to the manubrium and midaxillary line. The gas gradually disappeared and was entirely gone by October 22. At no time were there present any signs or symptoms of local inflammation. Patient now convalescing.

Laboratory Findings: (*A*) Culture from Pus in Pleural Sac: Streptococci.

Case XIII.—Private D., Company D, 306th Ammunition Train, admitted October 8 with diagnosis of influenza. Further examination on same date showed a patch of bronchopneumonia in the right upper posterior lobe which spread, involving the whole right upper and middle lobes and left lower lobe by October 15. On October 17 a distention of the skin was first noticed in the supraclavicular fossæ and neck. Palpation over the involved area gave crepitation characteristic of gas in the subcutaneous tissue. By October 19, at the time of death, the process had extended from the margin of the jaw to the fifth rib on both sides. At no time were there present any signs or symptoms of local inflammation.

Autopsy: Purulent bronchopneumonia present in the right upper and middle lobes and in the left lower lobe. Trachea and bronchi were very much injected. Cut surfaces of involved lung revealed numerous miliary abscesses. Gas was present, besides where clinically mentioned, in the mediastinal tissue and interstital tissue of the lungs.

Laboratory Findings Following Death: (*A*) Culture from Heart Blood: Gram positive diplococci. (*B*) Culture from Pericardial Fluid: Gram positive diplococci, pneumococci Type III (Avery). (*C*) Culture from Mediastinal Gland: Gram positive cocci, few. (*D*) Cultures from Left Pectoralis Major Muscle: Negative. (*E*) Culture from Left Pleural Sac: Gram positive diplococci. (*F*) Culture from Left Lower Lobe of Lung: Gram positive chains of cocci; gram positive diplococci; gram positive clusters of cocci.

Note.—Lack of time and facilities prevented further laboratory work such as urine analysis, blood counts, etc., during this epidemic.

History of the Development of Subcutaneous Emphysema.—Building No. 2 of the isolation group, where these cases first appeared, is divided into two wards, being connected by a kitchen between them as shown in the diagram inserted below. Until September 18 only patients with influenza had been taken care of in this building. On September 18 and 19 both wards were vacated of influenza cases (three remaining, as they had developed bronchopneumonia). As soon as the patients were evacuated, patients with bronchopneumonia were admitted, and by the evening of September 20 both wards, consisting of a total of forty-one beds, were again filled. These patients came from other influenza wards, a few directly from the receiving ward. There were two nurses and two orderlies taking care of patients in this building in the day time and one nurse and one orderly at night. The nurses and orderlies worked back and forth in both wards, as needed.

When making the rounds in the morning of September 23, 1918, one of the patients—Case 1, in Ward B, bed 9—had a peculiar elevation of the skin in the supraclavicular fossæ, as previously described. In the evening of September 25, Case 11, in bed 10, Ward B, developed. On the following morning, September 26, Case 3, in bed 8, Ward B, Case 4, in bed 5, Ward B, and Case 5, in bed 6, Ward A, had developed a similar condition. Isolation of the cases was at once instituted.

Ward B was evacuated of all other patients except two, who were dangerously ill. These two were kept in the opposite corner of the ward. (They died later without developing the subcutaneous gaseous condition.) Case 5 was moved into Ward B with the other patients. Case 6 developed September 27, in building No. 5 of isolation group. This building was some 500 feet away from building No. 2. Case 7 developed September 29, in building No. 6, which was just across the road from building No. 5. Case 8 developed September 30, in building "Y," which is far removed from any of the above-mentioned buildings. Case 9 developed October 4, in the infirmary of the 318th Field Artillery, located in a village outside of the post. Case 10 developed October 10, in building No. 1, which is adjacent to buildings 5 and 6. Case 11 developed October 16 in the Surgical Building, following rib resection for empyema. Case 12 developed October 17, in the Surgical Building, following rib resection for empyema. Case 13 developed October 17, in Building No. 5.

This group of cases was taken care of by one nurse and two orderlies, who did not come in contact with other buildings.

After the first case developed, isolation was instituted immediately upon detection of the condition mentioned. There has been no new case since October 17.

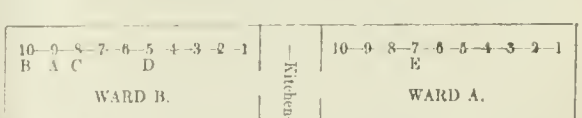

Diagram of Building No. 2, in which the above cases first developed. 1, 2, etc., bed numbers. A to E, order of development of cases in wards of Building No. 2: A, September 23; B, September 25; C, September 26; D, September 26; E, September 26.

Résumé of Pathology Found.—The areas of emphysematous tissue showed no gross change, and gas which escaped had no odor, but had a tendency to aid combustion. In all cases air was found in mediastinal tissue, pericardial fat, and in most cases in the interstitial tissue of the lung.

Pleurisy was noted in a number of cases, usually

of a plastic type. In other cases it was rather gelatinous, especially on intralobar surfaces. One case was found that had empyema. The lungs usually showed an extensive involvement; that is, from complete consolidation of a lobe to disseminated nodules, while in most cases the middle of the lobe was solid, with periphery of the lobe tense as if filled with air under pressure, and on puncture of a small area around puncture collapsed. The right middle lobe was usually free except for a purulent bronchitis.

The cut surfaces of the lung had a miliary appearance, which was most marked in region of bronchicoles, where lung was grayish in color, and as it reached the periphery of solid area it became red, and here in a few cases small capillary hemorrhages were noted. On scraping the cut surfaces it was noted that the miliary looking bodies were small abscesses, varying in size from pinhead to a half centimeter in diameter. The lung tissue between these abscesses was broken down, almost gangrenous in cases. The cut bronchi exuded a mucoid, yellowish pus. Small scars were noted in a few instances on the surface of the lung. These scars were surrounded by a little area of hemorrhage and collapsed lung. Inflation under water failed to prove communication with a bronchus. The bronchial and peribronchial lymph glands were enlarged. A purulent tracheitis was present in nearly every case. Most cases showed an increase of pericardial fluid. The liver, in all cases, was congested and enlarged. The small bowel usually showed injection of mucosa in region of cecum.

Bacteriology.—It will be noticed after studying the laboratory notes on the above cases that the ordinary groups of organisms which are usually associated with findings in bronchopneumonia are present in these cases, but there is one organism found that was of special interest. A gram of positive bacilli was isolated from the blood in two cases prior to death, and in heart blood and gaseous tissue in four cases at autopsy. Four other cases of bronchopneumonia which did not have subcutaneous emphysema were cultivated at necropsy, with negative results. This series is so small that it means nothing, but a great amount of laboratory work at the time prevented further controls.

Methods Used in Studying Bacteriology.—Blood cultures were taken in the usual manner, and amount of blood used was from 5 to 15 c.c. This was put into glucose carbonate broth, 25 c.c. to 100 c.c., and two plates were made by putting ½ c.c. respectively into a tube containing 7 c.c. to 100 c.c. of an infusion of agar melted and cooled to 45° C. before putting into the blood, which is mixed and poured into a plate. This was incubated for 24 hours and examined.

A. Cultures which showed gram positive bacilli: 2 c.c. was taken out by means of a sterile pipette and forced out into the bottom of an infusion of agar or Veilon's medium, which had previously been melted and cooled to 56° c., then growth and gas formation studied.

B. Cultures showing gram positive diplococci were transferred to broth, and if the original plates failed to show a growth a loopful was streaked out on a whole blood plate. Precipitin test was done directly from broth after throwing down cocci. If this was negative, agglutination was done.

C. Cultures showing gram positive cocci in chains were transferred to a whole blood plate, unless original plate showed typical colonies, and then transfers were made to broth. (1) Bile solubility tried. (2) Hemolysis test, using rabbit corpuscles, was done.

Autopsy Culturing.—Cultures were taken from the pericardial fluid by puncturing the sac with a sterile pipette after searing it; blood was also obtained from the left ventricle in the same manner, after searing the heart surface, and cultured, using the method described above.

Cultures were taken from the pleural cavity by carefully drawing a small amount of fluid found in the sac into a sterile pipette and later streaking it out on a whole blood plate, while a piece of lung was put into a sterile Petri dish, and later cultures made of surface on blood agar plates.

Cultures from emphysematous areas were made by carefully removing a small piece, as for example, a piece of pectoral muscle or mediastinal gland, etc., and put into a sterile Petri dish; and then in the laboratory, after searing the entire surface, a small piece was submerged into a tube of g ucose, an infusion of agar, or Veilon's medium which had been melted and then cooled to 56° c., and after inculation it was cooled under a tap. These tubes were incubated for 24 hours and then studied for gas formation. Those which did not show gas were incubated for two to six days and then studied. Following this, transfers of cultures were made of tubes showing gas to Veilon's medium, stabs, and to broth for animal inoculation.

Gas-Producing Bacilli.—The organism isolated in four cases was a rather large gram positive bacillus, nonmotile, having rounded ends. And in seven days old culture spores were present at one end of the bacilli. No capsule was demonstrable. It was acid fast. In a few old cultures it was noticed in diplos, but chains were never seen.

Culturally it grew in deep stabs, never on the surface, and the more luxuriant growth was always in the bottom of the stab, with formation of gas and breaking up of media. In secondary cultures gas appeared after 48 to 72 hours.

Animal Inoculation.—A 12-hour-old broth culture was injected into the marginal vein of an ear of a rabbit. In 15 minutes the animal was killed and put in incubator. In 5 hours the rabbit was found distended, and the tissues contained gas. At autopsy all the organs were foamy, and the bacilli were found in the liver, spleen, and heart's blood. The gram positive bacilli recovered from these organs showed the same morphological and cultural characteristics as the organisms injected into the vein.

The gram positive bacilli injected into the peritoneal cavity of a guinea pig produced paralysis of the hind legs in 18 hours and death in 29 hours. Autopsy showed peritoneum injected and bowel distended, the liver contained gas, culture from the heart blood was negative, culture from the liver showed a large bacillus having all the morphological and cultural characteristics of the organisms injected.

Conclusion.—From a study of the clinical data, the explanation as to the etiology of this complication divides itself into two phases: First, the possibility of its being of passive or mechanical origin; second, the possibility of its being an expression of a bacterial invasion.

In considering the mechanical theory, it is important to note that the first appearance of the subcutaneous emphysema was in a region where one might expect a mechanical emphysema to appear, as in the supraclavicular fossæ, neck, axillæ, over the pectoralis major muscle, and then its spread into adjacent tissues in a fairly rational sequence, following lines of least resistance fairly well based anatomically. And further, the finding of small scars on the lung surface, which in a few cases seemed to communicate with a bronchus; but inflation under water failed to demonstrate any openings. Also the lack of symptoms, both local and general, tend to point toward a mechanical origin. As was noted from the clinical records, only one patient (CASE I) complained of local pain, and here the distention itself was great enough to cause this symptom. And at necropsy the emphysematous areas were not injected, edematous, or in any way showed signs of inflammation, as might be expected in a bacterial invasion. From the study of the charts no evidence, one way or the other, from the pulse, respiration, and temperature curves could be gained. The only sign noted that seemed to increase with the appearance of the emphysema was cyanosis. Whether or not this was an expression of the pneumonia involvement alone, or a combination of the pneumonia condition with the gaseous process, we are unable to say.

On the other hand, there are many strong points in favor of a bacteriological origin. First, there developed in one building five cases, within a period of three days, four of which were in one ward, and three of which were side by side. It seems rather far-fetched for a coincidence of five cases with ruptured lungs to develop within a period of three days in one ward, and further, that three of the cases should be side by side. There were two possible modes of transmission of an infection in these five cases: (1) By direct transmission, through droplet infection (yet the cubical system of isolation was used, making it practically impossible); (2) by indirect means, as by nurses, orderlies, drinking cups, etc. In the remaining eight cases no evidence of contact, either direct or indirect, could be traced either before or after they became sick. But certainly the first five cases point to the complication being of a contagious nature.

Second, the appearance of the subcutaneous emphysema in practically all of the cases in a definite period of the disease; that is, occurring on the lysis temperature curve 3 to 5 days following the maximum temperature, except in empyema cases, where it developed following operation. And further, that the subcutaneous involvement ran its active course in two days, except in CASE I, where it ran for five days. If the process was a mechanical affair, we cannot see why it should appear at a definite period of the disease and then run a definite course.

Third, the local involvement, in a way, appeared to be a progressively mechanical affair, yet the gas spread up and down from the initial involved area irrespective of origin or insertion of tendon sheaths or fasciæ; as in Case I, it extended from the finger tips to neck, trunk, and below Poupart's ligament; and also gas was found in cases that came to necropsy, in the interstitial tissue of the lungs, thus pointing to a bacterial invasion.

Fourth, it is noted that these cases that came to necropsy present a different pathological finding in the involved lung from that of ordinary bronchopneumonia alone. Here not only was the involvement extensive, but cut surfaces revealed numerous miliary abscesses which are not present in ordinary bronchopneumonia, and were not present in the great number of uncomplicated bronchopneumonia cases that came to necropsy during this epidemic. This fact would lead one to think that these lung findings were a part of the subcutaneous emphysema process, and so further the theory of bacterial origin.

Fifth, the finding of a bacillus in the blood in two cases prior to death, and in four cases after death in the heart blood and emphysematous tissue; and further, that this bacillus produces gas, lends more weight to bacterial theory. The fact that this bacillus could be cultured, injected into a rabbit, producing a like condition as in man, and then recovered, producing gas again in media and having the same morphological characteristics as the initial organism, tends to show that it is a specific organism. While not enough controls were run (only four) to establish definitely the absence of the organism in other cases of bronchopneumonia, yet one feels reasonably sure we would not have found it present.

From so small a series of cases, limited time and facilities, no definite conclusion may be drawn, but it is curious to note that from the history of the subcutaneous emphysema it appeared to be infectious; it occurred at a fairly definite day of bronchopneumonia; it had a definite active course; it had a definite type of pathology, and a gas bacillus was isolated in four of the thirteen cases. While no definite grouping or classification of the organism can be made at present, its morphological and cultural characteristics tend to place it in the *B. welchii* group.

If the complication above described is due to a gas-forming organism, it seems plausible to believe that its mode of entrance is through the respiratory tract, the organism reaching the consolidated areas of lung; there in the broken-down necrotic tissue, a good anaerobic medium being furnished for the gas bacillus, where it multiplied, spreading by continuity or blood stream.

While the foregoing data prove nothing definite, they may be of some value to workers in the future; and to the clinicians it may be said that all cases of subcutaneous emphysema following pneumonia should be isolated.

The Blind of Mexico.—Of a total population of 15,000,000 Mexicans, 12,000 are totally blind. The ratio is therefore 78 per 1,000, which shows a considerable decline from former years. The three chief causes are smallpox, ophthalmia neonatorum, and purulent ophthalmia. The number refers only to the registered blind and nothing is said of unregistered cases.—*El Siglo Médico.*

THE STICKING POINTS IN DEVELOPMENT.

By CASPER L. REDFIELD,

CHICAGO.

WHEN a man takes up physical training he builds up strength in the muscles he exercises. That strength—sometimes designated as power—is built up by exercise is well known, and that fact is taken advantage of by pugilists, wrestlers, oarsmen, etc., who go into training before going into a contest. The recent war gave us a good many millions of examples of strength being built up by exercise. After soldiers have had some months of training they are much more powerful than they were before.

The reverse is also true. When an athlete takes up a sedentary life, his muscles gradually lose the power they had before. A sedentary life is not a life of absolute quiescence. It is simply one having in it a reduced amount of exercise, and when the exercise is reduced to a point below that necessary to keep muscles from degenerating, it is properly called "idleness".

The point to be made here is that organs have their powers developed by exercise, and that these powers degenerate by idleness. Organs are composed of cells. Hence, the increase of power by exercise, and the loss of power by idleness, are physiological changes occurring within the bodily cells.

When we first undertake to reproduce a plant by cuttings we often find it difficult to make it grow that way. But if we take a cutting from the first plant raised from a cutting, we find that the second one will grow more easily than the first one. If we take a cutting from the second plant produced that way, we find that the third grows still easier, and so on.

Here again we have a case of power being built up by exercising it. But when a plant is continually reproduced by cuttings it is not being reproduced by seed, and when it is not being reproduced by seed it is not exercising its seed-producing power. The result is that plants which are reproduced regularly by cuttings gradually lose their power of producing seeds, or seeds which will germinate.

The building up of power by exercise, and the loss of power by idleness, operate the same in plants as in animals. And the changes which occur are physiological changes within the cells of the plants. It is not material that we do not know the physiological nature of these changes. It is sufficient for our present purposes to know that they are changes in power as distinguished from those physical characteristics which are observable to the eye, or may be measured in feet and inches.

The "dope fiend" habitually takes amounts of poison great enough to kill a man not accustomed to taking it. The dope fiend does not survive the taking of such large doses because he was born with greater powers of resistance than other men. He does so because he began with small doses, such as any man might take and survive, and then gradually increased the doses as his powers of resistance developed by exercising them. Here again the change is a physiological change occurring within the cells of the body as a result of exercising such powers as existed in the first place.

The flagellata are unicellular animals which live in water and reproduce by fission. During a period of about six years (exact time not stated), Dallinger subjected these animals to gradually increasing temperatures. Beginning with animals living in water at 60° Fahr., he occupied about two months in raising the temperature to 73°. At 73.5° some deaths occurred, and for some time it was found impossible to get by this point. It required two months' time to raise the temperature from 73.5° to 74.5° and keep the animals alive. After getting by this pjoint it was found that the temperature could be raised more rapidly, but at 78° there was another and more serious sticking point. For eight months it was not possible to raise the temperature above 78° so much as one-half of a degree and keep the animals alive.

But once past this sticking point at 78°, progress was more rapid, though not uniform. He finally got the temperature up to 158°, when the experiment was terminated by accident. Raising the temperature from 60° to 158° in six years means that these little animals could stand an average increase of temperature of about sixteen degrees per year, or one and one-third degrees per month; but not uniformly. At one time it required two months to raise the temperature as much as one degree, and at another time it required more than eight months to raise the temperature less than one-half of a degree. On the other hand, the temperature was raised from 107° to 137° in seven months, and from 142° to 158° in three or four months.

These little animals built up their powers of resisting the effects of heat on their protoplasmic substance by continually exercising such powers as they had in the first place, and such as they acquired on the road toward resisting higher and higher temperatures. The thing to be noted here is that while the efforts of the individuals were comparatively uniform, the observable progress was very irregular. At two different periods, separated from each other, these animals gained in resisting power at the rate of about four degrees per month for several months in succession. At another time it took them two months to gain one degree, and at still another time it required eight months for them to advance one-half of a degree.

We have no means of knowing what caused these "sticking points" which it required these little animals so long to overcome, but we may assume that it had something to do with the molecular structure of their bodies. An analogy will help us to understand that such things might be expected, even when we have no means for determining what actually happens. For example, if we continually raise the pressure of steam in a steam boiler, we finally come to a time when we can raise it no further without causing an explosion and consequent destruction of the boiler. But if we shift our efforts for a time from pressure raising to thickening or bracing the boiler shell, we can resume the process of raising the pressure. But after a time we must again pause to thicken

or brace the shell before we can pass some other point which we might call a "sticking point".

Let us take an analogy of a different kind. If we apply heat to ice at zero, each addition of heat will raise the temperature of the ice until we get to 32 degrees. Here we come to a sticking point. For a time, further addition of heat does not raise the temperature. It results only in changing the material from ice at 32° to water at the same temperature. But as soon as that change is completed, each addition of heat increases the temperature until we come to another sticking point at 212°. Here, for a long time, further addition of heat does not raise the temperature in the least. It results only in changing the water into steam which is of the same temperature as the water. This point passed, further addition of heat increases the temperature until we find another sticking point at the point at which steam is disassociated into hydrogen and oxygen.

The development of power by continued exercise is well illustrated in the trotting horse. For example, we will take the case of the old time trotter, Flora Temple, who broke the championship record five times in succession.

HIGHEST SPEED OF FLORA TEMPLE AT DIFFERENT AGES.
ONE MILE.

Five years old	2:49
Seven years old	2:36
Eight years old	2:27
Eleven years old	2:24½
Fourteen years old	2:19¾

Flora Temple was not raced as a six-year-old, but was raced at every other age up to and including sixteen years of age. She gained in speed at the ages of seven and eight, but did not gain at the ages of nine and ten. She gained again at the age of eleven, but not at the ages of twelve and thirteen. And again she gained at the age of fourteen but not at the ages of fifteen or sixteen. However, she was in only three races at the age of sixteen, partly because she could find few contenders, and partly because she was confiscated by the government early in the season. That was in 1861, and her owner was a southern sympathizer. But in those few races she came within three-quarters of a second of her best previous record.

Looking at the record of Flora Temple, it is fairly evident that the development of her trotting power under continued trotting exercise came to a sticking point when she was nine and ten years of age; to a second sticking point when she was twelve and thirteen years of age; and to a third sticking point when she was fifteen. The indications are that she would have gained in speed as a sixteen-year-old if her racing career had not been prematurely cut off.

HIGHEST SPEED OF GOLDSMITH MAID AT DIFFERENT AGES
ONE MILE.

Eight years old	2:36
Nine years old	2:30
Ten years old	2:24½
Eleven years old	2:22½
Twelve years old	2:19½
Fourteen years old	2:17
Sixteen years old	2:16
Seventeen years old	2:14

Goldsmith Maid was raced every year from the age of eight to the age of twenty. Looking at her record it will be seen that she gained in trotting power under continued training up to seventeen years of age, but that the gain was not uniform. She made no gain at the ages of thirteen and fifteen, or after seventeen. But at nineteen she equalled her best record, and at twenty she came within one-half second of it. It seems evident that there were sticking points at the ages of thirteen and fifteen.

The production of milk by a cow is an example of work performed by animal powers. Normally, cows are milked with great regularity, which means that their milk-producing powers are continually exercised. The result of this is seen in the fact that cows produce more milk when they have their second calves than when they have their first ones; still more when they have their third calves; more yet when they have their fourth calves; and so on. This may be seen in a table which classifies cows by their ages.

HOLSTEIN-FRIESIAN MILK PRODUCTION.
Seven-Day Official Tests.

Average Age.	Pounds of Milk.
Two years and two months	322.7
Three years and two months	400.3
Four years and two months	446.8
Six years and six months	450.7
Seven years and seven months	472.6
Eight years and three months	499.8
Nine years and seven months	564.8

The first half of this table is just as it is furnished by the Holstein-Friesian Association for 1913. The second half is a tabulation made by me from the records of 1906. The reason why it was necessary for me to make this tabulation is because the association does not classify cows over five years of age, but lumps them all together. In this tabulating I followed the same cows through successive years of lactation. By this process I learned two things. The first is that taking the average of all cows, they increase in milk-producing power from year to year up to at least twelve years of age, which is as far as the records show the same cows tested in successive years. The second is that the actual increase is confined to about two-thirds of the cows, the other one-third either making no increase in milk-production or showing an actual falling off. The cows that failed to show an improvement in the second year over what they did in the previous year were found at all ages from six to eleven. Evidently, cows normally increase in milk-producing power year by year under milk-producing exercise, but there are "sticking points" in this improvement. Also, these sticking points come at different ages in different cows.

Mental power is developed by mental exercise the same as other powers are developed by corresponding exercise. The Binet system recognizes the growing mental development of children by establishing standards which represent normal-mindedness for different ages. By other tests it is seen that continued mental development resulting from continued mental exercise extends through adult life to comparative old age.

While mental powers are developed by exercise, year by year up to old age, there must be

sticking points in that process the same as there are sticking points in other processes of the same nature. Also, these sticking points must vary in quality the same as they do in flagellata, and the heating of hydrogen oxide, and they must come at different times in life for different persons the same as they do in horses and cows. The failure to recognize the existence of such sticking points, and to take them into consideration in the treatment of school children, must result in much injustice.

A child does fairly well for a time in school, and then comes to one of these sticking points. Continued efforts produce no observable progress, and the child is called dull. If the sticking point is a particularly tough one, he is called stupid or feeble-minded. In due time the child learns that he is looked down upon, gets discouraged, and ceases to try. By this process, a sticking point which was purely physiological and only temporary in character becomes psychological, and the psychological sticking point reacts upon the physiological one to make it permanent by stopping all efforts to get over it.

The remedy is to recognize the fact that all sticking points may be overcome by persistent efforts. Omitting idiots and persons having some organic mental defect which would correspond to a person born without legs, it is an error to assume that a person characterized as feeble-minded cannot advance in mental development. He can and certainly will advance if efforts are continually made to overcome each sticking point as he comes to it. If a child is encouraged and made to understand that he is only up against a temporary sticking point and not up against a dead wall, he will redouble his efforts and overcome that point so much more quickly. It may be that some sticking points are so tough that it will not pay to try to overcome them, but we have no right to take that attitude until after we have tried out and carefully measured the qualities of many sticking points. Also, we should distinguish those which are psychological from those which are physiological.

525 Monadnook Block.

IN DEFENSE OF THE WHITE OPERATING ROOM.

By WILLIAM LEE SECOR, A.M., M.D., F.A.C.S.

KERRVILLE-ON-THE-GUADALUPE, TEXAS.

SURGEON, KERRVILLE SANITARIUM HOSPITAL.

During the past two or three years a number of articles have appeared in medical journals, in journals devoted to architectural problems and even in the daily press advocating the use of tinted walls for our operating rooms. Dark green wainscote, green or black sheets, towels, and operating room furniture.

These different agencies are interested in this subject from entirely different standpoints—the medical journal as a problem in hospital efficiency—the journals of architecture from the standpoint of an innovation in operating room construction which offers new possibilities for pleasing effects and the utilization of various colored tiles and enamels recently placed on the market for this purpose—and the lay press from the standpoint of publishing anything new or sensational.

We as surgeons should give the problem of proper operating room illumination more study and consideration. We are the ones to solve this problem.

Some of our most costly hospitals bear striking testimony to the fact that architects may spend millions and produce very impractical results.

Dark green walls or wainscote are offered as a remedy for the glare evil that most of us recognize as a real evil causing discomfort for the surgeon and hindering him in doing his best work. The problem that we are called on to solve is not as to whether the glare evil exists or not, but what is the best remedy for it that can be found.

In the *Modern Hospital* for September, 1917, I published an article setting forth what seemed to me to be a solution of this problem. Since that time I have received many letters from all over the country testifying to the satisfaction found in following out suggestions offered in that article.

What are the essential qualities of a perfect operating room? They may be summed up under the head of efficiency. The more nearly perfect the operating room the more efficient it will be. It should be so planned that in form, arrangement of adjoining rooms, location of apparatus, illumination, heating, ventilation, and ease of cleaning that the greatest amount of work can be accomplished by surgeons, nurses, and orderlies with the highest degree of comfort and the least amount of effort.

Aside from general efficiency, the subject of the psychic influence of the operating room upon both patient and nurses is one that should receive due attention. In the smaller hospitals where general anesthesia is induced in the operating room, it is of considerable importance, but it is in the operating room used for local anesthesia where the full importance of this subject is felt. Here everything of a psychic nature that will allay fear and give confidence is of the greatest importance in aiding a perfect anesthesia. Surgical assistants and operating room nurses require long training to perfect an "aseptic conscience" and we are of the opinion that pure white surfaces about the operating and sterilizing rooms act as constant reminders, awaken suggestions of cleanliness, and thus aid in this training.

One of the most important essentials of a good operating room is proper illumination, both natural and artificial. In considering the illumination of the operating room from the surgeon's standpoint we may divide operations into two general classes. Those done in deep cavities and those done on or near the surface. These two classes of operation require distinctly different types of illumination.

In eye, ear, nose, and throat work, vaginal, rectal, and some deep pelvic work, the field can be better illuminated by concentrated light upon the operative area than by the general illumination of the operating room. For this kind of work

dark green or black walls are just as good or probably better than white walls.

This type of strongly concentrated illumination may be obtained by a projection lantern and secondary pivoted mirror reflector as was first used in some European hospitals, or may be obtained by a powerful lamp with or without lens attachment and either suspended from the ceiling or attached to the floor stand.

The strong illumination of a cavity is an essential in many special operations but is only occasionally required by the general surgeon if the operating room has efficient general illumination. It has the great fault of deep shadow formation.

The ideal illumination of an operating room would provide for an abundance of soft light to come equally from every direction. The illumination obtained in the open air at noon on a day when there is an even cloudiness just sufficient in density to obscure the exact position of the sun is to my mind about as close an approach to the ideal as we could get.

One of the most important requirements of the proper lighting of the operating room is that there shall be no shadows and this is one of the hardest problems that we have to solve in artificial illumination.

The farther we get away from the fact that light should come from every direction and the more we limit the area of the source of illumination and the surfaces about the room from which light may be reflected the nearer we get to shadow formation.

In an operating room with dark green sidewalls in which the light is admitted from one side only, with the addition of a skylight, there would of course be a light side and dark side to everything in the room. Shadow formation would be inevitable.

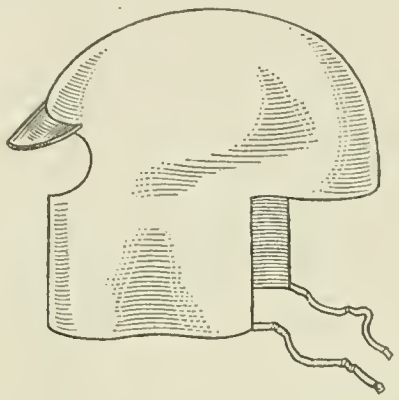
In order to solve the problem of illumination and efficiency, I built my operating room with an octagon floor space, twenty-four feet in diameter. Three panels of this octagonal room and a skylight with a northern exposure are constructed of heavy sanded glass which has one undulated surface to aid diffusion of light. The vertical sidewalls are ten feet high, from which level the eight ceiling panels slant toward a central horizontal octagon panel, the space above this ten foot level forming a truncated octagonal pyramid.

While this construction gives an excess of light at certain hours of bright days we think that this excess can be much better cared for and the evils of glare prevented by wearing what is now known as the Mayo-Secor cap, and glasses with properly tinted lenses than by coloring the operating room walls and using black sheets, gowns, and towels.

When glasses fitted with large lenses of Noviol or Crookes glass are used, the irritating violet rays are eliminated with very little interference with illumination or color values. If these glasses are treated with one of the preparations in use to prevent steaming they will cause the operator no inconvenience whatsoever and may protect him from the loss of an eye due to direct infection, an accident which has cost more than one surgeon an eye.

The majority of surgeons wear glasses for the correction of visual defects, they should have a special pair with properly ground and tinted lenses which should be kept in the surgeons' private locker or instrument cabinet, clean and always ready for service.

The Mayo-Secor cap is similar to the original Mayo cap except that it has a visor of several thicknesses of the cap material, and the skirt is cut away at the back which makes it much cooler. This cap is easily made and seems to appeal favorably to every surgeon who tries it.



Mayo-Secor surgeon's cap for use in the white operating room.

While this construction of the operating room gives us excellent daylight illumination it also enables us to secure very satisfactory artificial illumination. A large semi-direct fixture fitted with powerful nitrogen globes of Crookes glass is suspended from the horizontal ceiling panel. The light from the fixture is reflected from the white slanting ceiling panels toward the operating table and the result is a soft general diffused illumination of the whole operating room with very little shadow trouble. This makes unnecessary the special types of operating table illuminators, some of which would serve better for thermotherapeutic practice than for lighting the operating room, and would give better results if applied to the surgeon's spine or feet than to his head.

We are of the opinion that white floor and sidewalls, white sheets, towels, and gowns all play a part in producing an evenly diffused light throughout the whole operating room.

Some of the operating rooms which have recently been constructed with dark green sidewalls receive 100 per cent. of their light from one side and reflect back only 11 per cent. (coefficient of reflection for dark green) from three sides. If the head of the table is toward the light either the surgeon or his assistants cast shadows and if the foot is toward the light you could get no good Trendelenburg illumination. Artificial illumination would be very frequently required and an unnecessary item of expense added.

In the white operating room about 100 per cent. of light enters from one side and 88 per cent. (coefficient of reflection for white) is reflected back from every surface, producing a much more even general illumination which is better in all but cavity operations as before noted.

Architects are not alone in failing to appreciate the bearing of preoperative psychic impressions upon postoperative end results. Some able

surgical technicians totally disregard this subject. But the next few years of surgical progress will bring it into its own.

A short time ago I was visiting, with a surgeon friend, the operating room of the hospital of my alma mater in Philadelphia. The surgeon operating at the time is a devotee of the black sheet and towel. As we passed out after the morning's work I said to my friend, "Well, how do you like that technique?" The surgeon replied, "The technique was all right, but the drapery was too funereal for me."

It is a very common thing to hear visiting ladies viewing our operating room say, "Oh, how beautiful! I would not dread an operation here, everything looks so white and clean."

Some think that the esthetic and psychic effect of a white operating room is due to habit and custom. Possibly this is true but as far as we know white has been the symbol of cleanliness and purity from time immemorial and we are of the opinion that it would take several generations of educational effort to efface the unconscious psychic impression inherited through the ages. If it is a habit it would be a hard habit to break.

We think that most major operations should be considered more in the light of weddings than funerals. A union of new life with a body otherwise past normal function, there should be occasions for songs of joy and springtime and not weeping and wailing. Nothing whatsoever of a depressive nature should enter into the surrounding of the surgical unit. Some of my colleagues even go so far as to play the victrola as an aid in diverting the mind and securing a better anesthesia. Why not? The old regimen of mutilating surgery and high mortality has passed and the new era of constructive and preventive surgery is here. This may seem foreign to the subject but in the case of a great many sensitive or neurotic patients black drapery about an operating room would most certainly produce depressing suggestions.

Any hospital superintendent of experience will testify that janitor service obtainable to-day is good, bad and indifferent, with emphasis on indifferent. I think dirt is more readily detected upon white surfaces than upon color and poor janitor work can be more easily discovered. Spatters of blood and body fluids dried on tile surfaces are much more liable to be overlooked on a dark green surface than on a white surface. Possibly if perfect janitor or orderly service was always obtainable this would not mean so much, but as it is the more readily dirt can be detected by one in charge the surer we are of cleanliness. We believe that white surfaces increase housekeeping efficiency.

As we stated in the beginning it is not a question of whether glare exists or not, but a question of the best remedy for this evil.

Shall we endeavor to correct this condition by an alteration in the construction and finish of our operating rooms that will markedly lessen their efficiency, or shall we do it by a means that will add to the safety and comfort of the operator and his assistants and at least retain all of our present efficiency.

FATAL CASE OF ASPIRATION PNEUMONIA CAUSED BY THE INGESTION OF ZINC STEARATE.

By GUSTAV F. BOEHME, Jr., M.D.,
NEW YORK.
CONSULTING NEUROLOGIST, POLICE DEPARTMENT OF NEW YORK; PSYCHIATRIST, EDUCATIONAL CLINIC, COLLEGE OF THE CITY OF NEW YORK; ASSISTANT, NEW YORK NEUROLOGICAL INSTITUTE.

THIS case is reported as an example of the possible fatal termination of the ingestion and inhalation of a usually inocuous substance by an infant.

K. F., aged 15 mos., of mixed Japanese and American extraction, was born without instruments after a labor lasting thirty-six hours. At the time of birth artificial resuscitation was employed, as the child did not attempt to cry for about twenty minutes. He was breast fed, and his first year passed uneventfully save for a tendency to respiratory instability (slight "colds," chiefly rhinopharyngeal, and occasional evidences of bronchial involvement). Otherwise the child developed rapidly and normally. On May 3, at five P. M., the child in some way came into possession of a box of stearate of inc holding two ounces, and swallowed at least one ounce. The mother states that when she saw her child the mouth and throat were filled with the powder which also came from the nostrils with each respiratory movement. She cleaned out the nostrils and throat as well as she could. In the meantime the child had become somewhat dyspenic and the abdomen felt distended. The mother sent for the writer who noted the following: The child lay quietly, but with inspiratory and expiratory dyspnea. There was marked lateral movement of the chest, the abdomen was distended and tympanitic, and a mild degree of cyanosis was present. Pulmonary examination revealed fine rales over the whole chest—temperature 99°. The mother stated that the child had had a slight "cold" for four or five days previous to the ingestion of the powder. A tentative diagnosis of zinc stearate ingestion and aspiration, associated with previous bronchitis, was made.

The next morning the child was more markedly cyanosed, the respirations more dyspneic (rate 60) with a reversal of the pause and a slight expiratory grunt. The abdomen was less distended, having been relieved by enema and catharsis. The rales were coarser and more bubbling in character, the left base showed some dullness and evidences of a beginning consolidation; temperature 99°, pulse 150, of good quality.

The child was seen in consultation with Dr. C. Coryell at 5 P. M., and we agreed that the probabilities were that it had had a mild bronchitis which, due to the aspiration of the zinc stearate, was converted into a bronchopneumenia, with acute edema.

The chi'd d'ed at 12.30 the same night of acute edema and cardiac d'stention. There seemed at no time to be any evidence of toxic action by the drug ingested. The temperature just before death rose suddenly to 102°, the respiration rate rose to 80, was shallow and markedly obstructed. No autopsy was permitted.

This child undoubtedly died from an aspiration bronchopneumonia due to the inspiration of zinc stearate. The question of the actual toxic action of the zinc stearate arises naturally. This the writer believes can be negatived, as no case of such poisoning is known (so far as the writer is able to determine). He is cognizant of two instances of administration to adults or older children with no toxic effects. Witthaus, Sollman, Potter, and other authorities speak of no cases of poisoning by this emollient. Chronic zinc poisoning is described; the chloride and the sulphate have produced toxic results acutely. The dyspnea and the acute bronchopneumonia may be attributed to (1) the local astringent mechanical irritation and (2) the reflex irritation of the vagus causing a vagal bronchopneumonia.

Medical and Surgical Lessons of the War.

GUNSHOT FRACTURES.

By GEORGE EWART WILSON, M.B. Toronto, F.R.C.S. Eng.

TORONTO, CANADA.

MAJOR C. A. M. C.

If one looks into the works of surgery written before the Great War, and reads the pages devoted to gunshot wounds, he will not be profoundly impressed with the serious nature of such lesions. Comparatively few pages are devoted to the subject, and an air of finality prevails. As a consequence, when the wounded began to arrive in England in the early days of the war with violently septic wounds, there was a good deal of sharp criticism directed against the officers who were responsible for the treatment at the front, the prevailing opinion being that antiseptics were not being adequately and properly used. It was soon apparent, however, that surgeons had an entirely new problem to solve.

To properly appreciate the nature of fractures caused in modern warfare, a brief account of the various missiles is necessary. These, roughly, are rifle and machine gun bullets, shell fragments from high explosives or bombs, and shrapnel. The modern rifle bullet is more pointed than those used in previous wars, so that the center of gravity is farther back—and has a muzzle velocity of from 2500 to 2800 feet per second. During the first period of flight, in addition to the forward and spinning motions, there is a wobbling of the base resembling an ellipse, the apex remaining stationary. Later the bullet steadies down in its trajectory, and photographs taken by Prof. V. Boys and on exhibit among the war specimens in the Royal College of Surgeons Museum in London, show that a bullet in full flight has a cone or wave of compressed air in front of it.

High-explosive shells burst on percussion, when the casing is broken into numerous high-velocity pieces of various sizes and shapes, with ragged edges. Having been in contact with the soil, it follows that particles of earth can readily gain access to the wound. Fragments from bombs thrown by hand, or grenades, come under the same category, but have much less weight and velocity, therefore less penetrating power. Shrapnel holds a place intermediate between rifle bullets and high-explosive fragments. Besides the shrapnel balls, there is the fragmentation of the casing, but in neither is the velocity anything like that of a bullet or high-explosive fragment, so that penetration is not so great. Then it bursts in the air, and if the explosion is not fairly close to the object aimed at, comparatively little damage is done. But a rifle bullet may take in all the characteristics of a piece of metal from a high-explosive shell, by passing through the parapet, when it becomes irregular in shape. Bayonet wounds are so rare as to require no notice.

The amount of damage which a missile is capable of doing depends upon four factors, the weight, the velocity, the size, and shape. Only the first two are concerned with the energy stored in the projectile, but the latter factors are very important in determining the character of this destruction and the question of infection, since the more irregular the fragment the more likely to bring in clothes and mud. On the other hand, the damage done is dependent upon the nature of the tissue struck; the denser the structure the greater is the work done by the missile, and the damage is correspondingly increased. Hence it is that a rifle bullet in full flight striking the compact shaft of the femur will shatter it, while the same bullet may make simply a tunnel should it strike the cancellous tissue of the condyles. In the first instance the bullet on leaving the thigh has lost a great deal of its velocity, or, in other words, has done a large amount of work, while in the second instance, very little work was necessary to penetrate the spongy tissue, so that the velocity has not been greatly affected. As to the size and shape, it is evident that a large irregular piece of metal with sufficient energy to penetrate a bone will cause a great deal of splintering, no matter what the density, seeing that the missile is spinning in an irregular manner, and at each instant is presenting a different surface to the part. When fired at close range, a rifle bullet striking a bone will probably make a small entrance wound in the skin and blow a large area of the bone out through the large crater-like exit. This is due to what is termed "the explosive effect of the missile." To explain this, various theories have been advanced. The late Sir Victor Horsley experimented by firing into a mixture of clay and water made to resemble muscular tissue, and then filled the cavity with plaster of Paris. The mud was removed and a cast of the effect of the bullet obtained. He noticed that many lines of force were approximately at right angles to the direction of flight, and concluded that the explosive effect was due in large measure to the spin of the bullet. The view most generally held today, however, is that the cone of compressed air in front of the missile is responsible for it. But missiles do strange things and frequently upset pet theories. For instance, in certain cases, the entrance wound is larger than the exit, and again, at close range, a bullet will drill a small hole of entrance and exit in the skull, and without exhibiting any explosive effect whatever, and this in instances where there could be no question as to the accuracy of the distance traversed by the bullet.

Let us now very briefly consider the new problem which surgeons had to face in the early days of the war. Generally speaking, the treatment adopted where feasible was to cleanse the wound with some antiseptic, remove pieces of clothing and accessible fragments, and close it up. But is was soon apparent that such a procedure was disastrous and many men lost their lives as a result, so that very shortly an order came out forbidding the suturing of wounds. In short, we were back once more to the days before Lister revolutionized the science of surgery, and practically all the wounds except some caused by rifle or machine-gun bullets, reeked with pus or were infected by gas gangrene or tetanus. Several factors contributed to the result. The war was fought over territory which had been highly cultivated for centuries, and organisms abounded in the soil. The fighting was of a most strenuous nature, and in most instances darkness had to be awaited before it was safe to collect the wounded

so that in addition to the loss of blood the men had to endure long exposure sometimes beneath a baking sun and at others under intense cold. Often they had neither food nor drink, and lastly on account of so much high explosives in use even in the early days by the enemy, the wounds were much more extensive and severe than in all previous wars. Statistics are not yet available, but probably the relative proportion of bullet wounds is reversed as compared with previous wars, and instead of 90 per cent. bullet and 10 per cent. of other kinds, the proportion will be 10 per cent. bullet and 90 per cent. shell and shrapnel.

Before discussing the various gunshot fractures in detail, it will be necessary to give a short résumé of the treatment in general. As already noted in the early days, the wounds were left open and ample drainage provided. There followed a period during which a host of methods and remedies were employed to combat the sepsis. Lack of space prevents a full discussion of even the more important of these, and I will content myself by enumerating the commonest ones: Dakin's solution, Rutherford Morison's paste called Bipp (bismuth, iodoform and petrolatum), flavine, eusol, brilliant green, ether, hypertonic salt solution, saturated solution of magnesium sulphate, soap and water 1-40, iodine solution, quinine hydrochloride, salt tablets, the salt pack, albolene, and several others. Every method had its advocates, but there is no doubt whatever that Dakin's solution and eusol which is very closely allied to the former, were the most popular. But the very fact of their great variety was sufficient proof that none approached the ideal, and when once virulent organisms were thriving in a wound, antiseptics were not of much avail; so it became, every month, more apparent that the best treatment for sepsis was prevention. It was soon established that if a wound could be treated within a few hours after its infliction, and thoroughly excised, it could be sutured with safety. As a consequence a radical change took place in the organization of the medical units in the field. The casualty clearing stations, which were organized after the South African War, were, as their name implied, clearing hospitals with about 200 beds, situated four or five miles behind the line, and patients were transferred as rapidly as possible to hospitals farther back, where the main part of the surgical work was done. A complete change occurred. The casualty clearing stations were enlarged to take the place of the base hospital. Their numbers were largely increased, and completely equipped with *x*-ray and operating rooms, and surgical teams, consisting of an expert surgeon and assistant nurse and trained orderlies, were established to go from one C. C. S. to another so that in any given sector where the line was active, the operating rooms could be kept busy day and night by relays of teams. It is estimated that considerably over 50 per cent. of the wounds can be treated by excision and closure, the percentage varying with the fighting, since during a rapid retreat with very heavy casualties there would not be sufficient time to carry it out. There are three requisites for success: First, too much skin must not have been shot away; second, the technique must be perfect, and third, there must not be well-established signs of inflammation, which means that the bacteria have already gotten beyond the area which one usually excises. It is difficult and impossible to lay down general rules as to how long after the receipt of the wound it may be excised, but if possible, within 12 hours, although many have been successful after 24 hours. Besides the time factor, there is the question of the circumstances surrounding the patient since being wounded, as exposure under trying conditions so reduces the natural powers of resistance that the bacteria make rapid headway. In any case, the earlier the better (provided the patient is not too shocked to stand the necessary procedure). Up to four or five hours, it is difficult by means of smears, to demonstrate organisms, but every additional hour adds tremendously to the ease with which they can be found.

Of the essentials for success, the technique is far and away the most important. As a rule, a general anesthetic is necessary, although some surgeons work with local, but if the wound is at all extensive, the former is much more preferable. Let us take, as an example, a comminuted fracture of the shaft of the humerus, in which a large piece of high explosive has laid open the front of the arm. The patient, having already had an immunizing dose of antitetanic serum, is taken to the operating room and anesthetized, preferably by warm ether. Then the more or less mud-caked clothes are removed. By not disturbing the patient till anesthetized there is much less addition to the shock which is present. The surrounding area is now just as thoroughly cleansed as is done in civil practice before a laparotomy, while the wound is protected with gauze. Any foreign bodies or pieces of clothing are now removed from the wound. With fresh gloves and gown, the surgeon then prepares to excise the wound. Grasping the edge of the skin with mouse-toothed forceps, by means of a very sharp scalpel, the whole of the possibly infected area is removed at a distance of one-quarter of an inch and upward and in one piece so far as that is possible. If there were no important nerves or vessels close by, and if the bone were intact, complete excision would be feasible. It is important not to allow the point of the knife to enter the wounded area during the dissection so that great care must be exercised in avoiding pockets, due to the contraction, for instance, of muscles cut transversely. Getting into the possibly infected areas courts disaster. In the case under consideration, then, the whole of the infected soft tissues have been excised. What now is to be done to the bone? All obviously loose splinters are to be removed. It is true that a comminuted fracture will unite better than a transverse break, but nonunion is nothing in comparison with infection. It is an established fact that micro-organisms in early cases are most readily found in the neighborhood of pieces of clothing, so that should such be in contact with the bone splinters, they should all be removed even though considerable shortening results. Some surgeons stain the wound with brilliant green to render the excision easier or it may be necessary to put one hand into it as a guide, but of course, the soiled glove must be changed immediately afterward. The next important step is to stop all bleeding. When this cannot be done, it is not safe to suture the wound, but it should be packed with gauze and sutured in 24 or 48 hours by what is

termed "delayed primary suture," in contradistinction to secondary suture, which is the suture of wounds after suppuration has ceased. Having satisfied oneself regarding the hemorrhage, the wound is ready for suture. If possible, silkworm-gut sutures are inserted to draw the edges together in their entirety, leaving no dead spaces into which serum will collect. Otherwise, the area is closed by catgut in layers and dry gauze dressings and bandages. The limb is carefully splinted and the man is kept at rest for a week. Complete rest is most important; so much so that unless one is assured that it can be given, the closing should not be done. Even in severe wounds without fracture splinting is necessary.

It would be a great mistake to get the idea that the above outline of treatment had become the routine in the armies early in the war. Curiously enough, the cue to the proper line of treating gunshot wounds came from the disastrous results obtained by putting tubes into the knee joint to avoid sepsis. It soon became apparent to the most casual observer that the tubes were doing not good, but a great deal of harm and the lessons regarding the knee joint learned by van Bergmann in the last Balkan war were doubtless an inspiration to trying a similar plan of treatment. In any event, tubes leading beyond the synovial membrane were discarded early in the war and with great advantage to the wounded. Excision was practised extensively in 1915, but it was not until the last year of the war that compound fractures were commonly treated by excision and primary or late primary suture. Toward the close of 1917, a series of experiments were made in different sectors. In one center wounds of all kinds, including fractures, were treated by excision and primary suture as detailed above; in another this same treatment was carried out, but the wound was flushed with 1-1000 solution of flavine before suturing, while in the third, the wound was washed out with a 1-40 solution of hard soap before closing. The results were equally good in all, over 95 per cent of the cases showing primary union, so that the conclusion forced upon the observers was that antiseptics were to say the least superfluous. It is not contended that no bacteria are left in the wound after primary suture. There is no doubt whatever but that a certain number are left behind in the majority of cases. But in no case is dead tissue allowed to remain and that is one of the most important features, for dead tissue has no power whatever to combat infection while the living, if given sufficient rest, is a much more potent factor than we have heretofore appreciated.

We are now in a position to consider some of the more important gunshot fractures in detail, and shall begin with those involving the skull.

Skull.—Gunshot wounds of the skull present great variations, from the worst cases where the top of the head is blown off to a mere fissuring. Like gunshot wounds in general, fractures are hard to classify as there are so many individual variations. Those coming for treatment may be divided into four classes:

1. Tangential fractures or gutter fractures.
2. Direct impact, causing fracture, but missile does not penetrate skull.
3. Penetrating fractures.
4. Diametral or through-and-through fractures.

From the practical standpoint, they may be divided into (1) those which cause a tear in the dura, and (2) those which do not.

First as to the appearances of the scalp. In many cases a glance will suffice to determine the serious nature of the wound, but there have been again many mistakes made and men have been treated time and again for scalp wounds when there was a fracture and cerebral complication. It is remarkable how slight is the shock in many cases of extensive laceration of the brain, and men have come into the dressing station supporting part of their brain in their hand. So that unless a careful examination of the scalp be made, serious lesions may be readily overlooked. So all scalp wounds are looked upon as skull injuries until the case is proven otherwise. In certain cases, the scalp wounds are typical. In a perforating bullet wound, the entrance is usually small and roughly circular. The glancing bullet, provided it has not been deformed by ricochet, makes either a long oval track or, if the soft tissues are thick enough, two small ovoid wounds with a bridge of scalp intervening. Irregular pieces make correspondingly irregular holes in the scalp.

As to the skull fractures themselves the commonest type seen at a clearing station is probably the tangential variety. These glancing missiles will produce a great variety of injury. The simplest is fissuring with no more damage to the inner table than to the outer, but this is exceptional. A more common type is to find a bruising or a slight gutter of the outer table, with slight or extensive splintering of the inner. In such a case, the dura may or may not be torn, and in the latter instance there may be several fragments of bone embedded in the brain. There may be a gutter in the scalp only, yet a depressed piece of inner table causing paralysis. Allied to this class of fractures is that of Class 2. In this instance, the missile has not penetrated the bone, but all grades of damage may ensue from simple splintering of the inner table without dural opening to fragments of osseous tissue driving into the ventricle. *Three*, Fractures due to penetration of the missile. Here the opening in the skull is dependent upon the size and shape of the missile. Fissuring is common and there is practically always extensive splintering of the inner table. In this class of case, the dura is of necessity opened and besides the metal there are usually small bony spicules embedded in the brain, and when both are present these splinters are practically never at a greater depth than the metal. In some the missile is near the surface, while in others it is far removed from the opening in the skull. *Four*, Perforating fractures, or through-and-through wounds. Naturally, this is a very severe type of injury and many of the wounded fail to reach surgical assistance. In some cases which reach the casualty clearing station there is complete loss of a large area of bone, with half an inch separation of a suture of the vertex. If the entrance and exit are fairly close together, the bone between is usually comminuted. In other instances, both openings appear to have been drilled with a burr, with no splintering, or fissuring, and with practically no symptoms. The usual thing, however, is to have splinters from the inner table driven into the brain.

The treatment of gunshot wounds of the head has been the subject of violent discussion throughout the war. We are not concerned with those who are so badly wounded that they only survive a few hours. What then is the best procedure? Early in the war it was found that head cases operated on at a C. C. S. arrived at the base in bad condition. The journey had been injurious. They found, too, that before operation they stood a two-hour journey by motor very well, and besides they were not so urgent, for example, as abdominal cases. Consequently, special hospitals were established a little farther back than the C. C. S., where these cases could be treated and kept till fit to travel. Before any operation is done, the whole head should be shaved, otherwise a second wound may be overlooked. As a routine he is given 10 to 15 grains urotropin every 4 hours. If a general anesthetic is to be administered, a quarter grain of morphine with 1 150 of atropine is injected beforehand, and a purgative is advisable. In most cases a general anesthetic can be dispensed with, in which case about an hour before the operation, a third of a grain of omnopon is administered. During this period a very careful neurological examination is made, and stereoscopic *x*-ray plates are prepared. Some prefer anteroposterior and lateral, but the former are preferable, and here one might note that too much reliance must not be placed upon the *x*-ray findings, especially regarding depressed fractures involving the inner table only. There may be a considerable depression, and yet not show in the plate, and again expert radiologists will report a depression when none can be demonstrated at operation. The proposed line of incision is now infiltrated with a 1 per cent. solution of novocaine or anocaine to which is added 10 to 15 drops of adrenalin to the ounce. The injection is made beneath the epicranial aponeurosis. Whether one turns down a flap or secures the necessary room by prolongation of the original scalp wound, the first essential is to excise completely the damaged skin, together with the pericranium. On no account must a flap be turned down before excising has been carried out, as sepsis is liable to follow. Having exposed the necessary area of bone, the next step depends on what is present. Even though the bone looks healthy, if the man is unconscious or is evidently suffering from intracranial mischief, the skull should be trephined and the inner table examined. Contrecoup disturbances can be left out of the question. Should the dura be found torn by splinters from the inner table, these must be carefully pieced together to see if any are missing. Should there be a deficiency, the dural opening is enlarged, if necessary, but very slightly, fearing breaking down of the adhesions, and a careful search made for the missing fragment. In this case there can be no possibility of infecting the brain since the skull in the outer table was intact. If successful in extracting the fragment the dura is sutured and the scalp closed, a drain of rubber tissue being left down to the dura for 24 or 48 hours.

Some surgeons hold that mere fissuring or even slight depression of the inner table are not indications for trephining. Should there be a gutter wound in the external table, the same line of treatment is followed, no matter whether the man shows any cerebral disturbance or not, for in all probability there will be a splintering of the inner table. But when the skull area is exposed and presents a comminuted area of bone the problem is more difficult. If possible, the fragments are elevated and thrown away. This is readily accomplished in some cases, but in others, it is necessary to make a small trephine hole at the side in order to get at the depressed pieces. In any case bone must be nibbled away until about one-third of an inch of normal dura is seen. If this is carefully done, sepsis from infected bone will be negligible. Should the dura be intact, the important question arises as to whether it should be opened or not. If it is opened, in all probability there will come out a quantity of devitalized pulped brain from the cone of damaged tissue, especially if the patient be asked to cough. When the dura is tense and discolored and does not pulsate there can be no question about the desirability of letting out the pulped brain, as there are numerous examples of symptoms promptly cleared up when such is done, but it is a dangerous procedure in cases where there has been an open communication between the scalp and dura. So that the consensus of opinion is largely against opening an intact dura. Subdural hemorrhage sufficient to cause any marked symptoms is so rare that it can be eliminated as a determining factor. In this connection it is instructive to note that Sargeant and Holmes, in their report to the British Government upon the later result of gunshot wounds of the head, found no deaths among those in whom the dura had not been penetrated, or opened by the surgeon. But if the dura has been opened and the missile retained, a still more difficult problem confronts the surgeon. He has presumably removed all infection from the scalp and bone—except that driven into the brain. The lacerated edges of the dura are cut away, but in no case should this be done freely or carelessly lest the thin veil of adhesions between the dura and pia-arachnoid be disturbed and a meningitis result. The track in the brain is now carefully explored, having in mind the *x*-ray picture. Any superficial fragments of bone or metal are carefully removed while if it is felt that more damage is going to be done to the brain in getting them out, than by leaving them in, no attempt should be made but the track in the brain drained. Obviously, there is grave danger in leaving possibly infected foreign material in the brain, but it is not justifiable to cause irreparable damage to the brain to lessen the danger of sepsis. Most surgeons in exploring the brain use the finger, but on no account must it be shoved far. Cushing uses a flexible soft rubber catheter to determine the track of the missile or fragments of bone and by attaching a Carrel-Gentile glass syringe with its rubber bulb to the end of the catheter he sucks out the softened brain. With the lessened tension he is then able by means of delicate duck-billed forceps to extract any fragment of bone or metal which is accessible. To extract more deeply placed missiles the magnet is the only justifiable means. Where there is great probability of infection in the brain it should be drained. This must not be effected by a rubber tube with lateral holes for the edema of the brain will very soon force softened tissues into the foramina. It is probably best ac-

complished by rubber tissue or jaconet folded concertinawise. In any case where there is a large defect in the dura, this must be closed and preferably by using a piece of aponeurosis. The scalp is then carefully sutured and where necessary sliding flaps are utilized to cover the cranial defect even though some other skin area be left denuded.

There is another class of fractures which deserves consideration and that is those which involve the superior longitudinal (sagittal) sinus. It frequently happens that splinters from the inner table are driven into the sinus. Bleeding occurs but in those which reach the operating table clotting will have taken place. To remove the splinters from the sinus is a procedure attended with very serious danger, for the hemorrhage is likely to be most profuse. To tie the sinus may be impossible, owing to the position of the hiatus in the skull relative to the sinus and packing may have to be resorted to. But either procedure is bad, for blocking of the sagittal sinus obstructs the blood in the cerebral veins with consequent edema of the brain with its serious sequelæ, so that the usual advice given is to leave such cases alone. If the method of Cushing be adopted, these sinus cases, however, will not present much difficulty. He encircles the area of depressed bone or the area where splintering of the inner table is suspected with a number of small punctures made with a perforator and burr connects these with a linear cut made by a de Vilbiss or preferably a Montenovesi cranial forceps and then tilts the whole skull segment out en bloc. If a fragment is left lying in the sinus, it can be removed, or if the spicule has come away with the segment, the bleeding area, for it may be half an inch square, is directly under the eye and can be immediately controlled by pressure while a muscle or fascial graft of the requisite size is prepared. The postage stamp graft, as it is popularly called, is spread out upon the palmar surface of the index finger, the pressure on the sinus is removed, and the graft quickly placed in position and held there for about three minutes, when it will in all probability adhere and check further bleeding. It might be added that Cushing uses the above method of removing the bone as a routine and not simply to expose the sinus. Injury to a lateral sinus presents no peculiarity since the blood may pass readily along the other side and so produce no symptoms referable to the circulatory system as does the sagittal channel.

Perforating or through-and-through wounds are of two varieties. In one there is an entrance and an exit, but the holes are so close together that the intervening bone is comminuted. This is simply an extension of the gutter fracture and is treated on the lines already outlined. In the second variety, both scalp and pericranial wounds are, as a matter of course, excised. These cases vary immeasurably. The majority doubtless are so badly shattered that they soon succumb, for the explosive force finds its best field in an incompressible substance like the brain. But at times the exit and entrance are as clean cut as though done by an electric drill, and with no explosive effects whatever. And there are cases where there is no more comminution of the inner table at the entrance than at the exit, but these are isolated occurrences. The usual thing is to have more comminution at the exit with in-driven splinters of bone. The treatment depends upon what is shown by the *x*-ray. If there are accessible fragments at either hole the dural edge is carefully excised and enlarged sufficiently to extract the pieces, always remembering the danger of breaking down the protective adhesions. Conservatism here is very essential. The great desideratum is to prevent sepsis, but not at the expense of cerebral mutilation.

The question of drainage in brain cases is a very difficult one. On the whole it is probably best not to drain unless one is forced to do so. Replacing the missile by another foreign body does not, on the face of it, appear very sound. But if there is definite pus, drainage must be provided for. Another indication is profuse oozing from a badly lacerated area, while a third is the presence of probably infected bony fragments or missile. But the mere presence of a metal fragment is not *per se* an indication for drainage, for if it has traversed the ventricle, and lodged at the base of the brain, no one would think of being able to drain it. Each case must be treated in its merits, and uniformity is scarcely to be expected since each surgeon, while

Fig. 1. Rifle bullet beneath the superior maxilla.

influenced by the opinion of others, is largely guided by his own past experiences.

Thus far, it is presumed that the cases have been seen early, that is before the advent of visible sepsis. When the latter has occurred, excision of course is out of the question and the only thing which can be done locally is to provide efficient drainage. And here, too, the protective line of adhesion must on no account be broken down.

Gunshot wounds involving the base of the skull, either in association with those of the vault or separate, are not as a rule amenable to surgical interference but are treated upon general lines, always excising the wound whenever possible to avoid the danger of infection and doing nothing to add further trauma to the brain. Occasionally a missile will be found to have penetrated the outer wall of the frontal sinus and lie free in the cavity without having injured the inner wall. Should a missile enter the brain via such a sinus, it is treated in the same general principles, but bearing in mind the possibility of infection arising in the sinus itself.

The mortality of gunshot wounds of the head is

difficult to state. Obviously it varies as one recedes from the front line. In any case, the operative mortality is well over 50 per cent. From the standpoint of prognosis the essential feature is the dura. If this has been opened, the prognosis is bad, no matter what the treatment, while if it is intact, the outlook is comparatively good. On the field the causes of death are hemorrhage and shock, while later on sepsis is the important factor. If meningitis supervenes, death is not often long delayed, especially if streptococci are present. Hernia cerebri is common and is always due to a septic encephalitis. It is treated by frequent lumbar punctures done under local anesthesia. Under no circumstances should the hernia be cut away, as in many instances the dilated ventricle is near the surface. It is a serious complication as may be judged from the report of Sargeant and Holmes, above referred to. Out of 120 cases that reached England with this complication, 24 per cent. died. Add to this the number who never became fit to travel, and the seriousness of the complication is apparent. The late prognosis is considered by the same authors as infinitely better than they had anticipated, as they found the death rate in England to be small, that abscess formation was comparatively rare, and serious sequelæ, like insanity and epilepsy, likewise infrequent even in those with retained missiles.

Gunshot Wounds of the Spine have a higher mortality than those in any other region in the body. In the Boer war, where there was an actual lesion of the cord with a fractured arch, 75 per cent. died, and those who survived were, in the great majority of instances, condemned to a life of misery and pain in a hospital for incurables. Like similar wounds elsewhere, the most severe in which segments of the spine are smashed never reach a place of operation. Many have associated injuries since the projectile may enter the abdomen or chest or even both. Either the body alone may be fractured or there may be fractures in addition of the laminæ. Not infrequent is a fracture of the transverse or spinous processes alone. While the missile usually comes from behind or the side, it may come from the front. In rare instances a bullet may enter by means of an intervertebral canal and lodge within the theca. As in the head, the dura may or may not be torn and either the missile or fragments of laminæ may lie within the dura. While the symptoms frequently show minor grades of variation, there is usually at first complete paralysis with involvement of the sphincters. The symptoms, in fact, are those familiarly met with in the fracture dislocation of civil life. In the early stage of many of these wounds a considerable part of the paralysis is due to traumatic edema and circulatory disturbances, and there is no means, outside of an inspection of the lesion, of knowing definitely during the first fortnight in severe cases whether the cord is divided or not. The same is true of peripheral nerves so that neurologists rely upon the progress of the case to determine the extent of the damage. Gordon Holmes lays stress on the tone of the muscles. If, after four or five days, it is good, improvement is to be expected, and if it is lost and the muscles start to waste the injury has been a severe one. Stimulation of the soles gives valuable information. If there is a withdrawal reflex movement, improvement is to be expected, while if no movement occurs, the damage is probably a very severe one. Later on, if the toes, on stroking the sole, show a plantar flection, in all probability no useful recovery will ensue. There is an additional factor, namely, concussion. It is not uncommon to meet with an instance where a man became paralyzed by the nearby bursting of a shell, and instances are plentiful where death has resulted, yet no bruise whatever was found on the victim. This paralysis usually affects the legs and at first there may be complete paralysis with involvement of the sphincters, although they usually escape. The symptoms, in fact, may be identical in their early stages with a severe non-recoverable lesion of the cord. It has been demonstrated by Gordon Holmes that even in slight injuries, for example, a fracture of the spinous process by a bullet, or even without any fracture, there is frequently associated a widespread damage to the cord in the nature of edema,

Fig. 2.—Bullet lodged in front of the sacrum

hemorrhage, softenings, and often in ascending cavity formation. These changes occur immediately or within a very short time after the wound.

It is evident, therefore, that it is impossible from the symptoms to say how badly is the cord damaged, and this has a most important bearing upon treatment. In the first place, if an operation is to be performed the sooner the better, provided there are no contraindications. The longer one waits the greater the danger of sepsis. Under no circumstances should the dura be opened, even in the absence of evident infection, since subdural hemorrhage causing symptoms can be discounted. As in the case of wounds in general, excision should be practised, but there are two indications for operation upon the cord: (1) where *x*-ray or direct examination reveals depressed bone or missile within the canal, and (2) where the patients suffer very severe pain. A good stereoscopic *x*-ray plate should be made and examined by an expert radiologist, but even then depressed fragments are often missed and

too much must not be expected from the removal of a depressed piece of lamina or the extraction of a missile. The damage in the vast majority of cases is done, at the time, and is not due to the pressure of the foreign body, and it is most important not to add to the damage already done by any operative interference. Late operations are dangerous in that infection is probably a complication and to disturb fragments which are projecting through the dura under such circumstances is a most dangerous procedure. I am aware that Symonds advocates such a procedure and lays stress upon the freedom from meningitis there is in the presence of sepsis, but I have seen patients succumb to a violent meningitis a few days after such a procedure, and am of the opinion that it is most dangerous and should be considered only if there is great pain and a reasonable hope of relief by operation. To expect alleviation of the paralytic symptoms from late operation is futile.

When operation is resorted to, local anesthesia should be adopted whenever possible, although some surgeons favor ether. No more of the laminæ are removed than is necessary and, when possible, the defect in the dura is closed by a fascial or muscle graft, no drainage being employed.

Those who do not die from hemorrhage and shock and escape cerebrospinal meningitis are very apt to develop bed sores, cystitis, and pyelonephritis and a great deal of careful nursing is required. To obviate the renal complications some surgeons have advocated suprapubic drainage and a goodly number of men are at the present time lying in hospitals with a tube still in the bladder. There can be no doubt that it does to a great extent lessen renal complications and in some cases that I have seen, over two years after the cystomy was performed, the bladders are able to hold six ounces. But there is always cystitis if the tube is left in for any length of time, and in old standing cases the wash water always contains numerous polymorphonuclear leucocytes. If it is done, a suction apparatus, such as a Sprengel pump, should always be attached to the cystotomy tube to keep the patient dry.

But if cystotomy is going to prevent cystitis it must be done early, and that is frequently impossible. Besides, a man with a tube in his bladder is difficult to transport in any comfort so that a primary cystotomy is not favored. It may have to be done later in very severe cases of hemorrhagic cystitis, in which catheterization is very painful. But if carefully done, regular catheterization is preferable. In most cases, after some weeks or months, the bladder gains a certain amount of control so that it fills and empties periodically just like the viscus of the infant, and when that stage is reached the catheter can be dispensed with and a urinal left between the legs of the patient with the penis lying therein, and from my experience, this reflex is more quickly acquired when no cystotomy has been done.

Lesions of the cauda equina have been of frequent occurrence. The cauda, as is well known, consists of the lumbar and sacral nerve trunks, and these can be sutured in the same way as a peripheral nerve. But just as it is impossible in a nerve in an early stage to say, except by direct inspection, that it is actually divided, so with these trunks, and if incompletely divided, with time recovery seldom will the opportunity be afforded to deal directly with the cauda equina. To Tuffier belongs the distinction of having successfully sutured a cauda lesion, during the war, and so far as I am aware, it is the only case on record where it was successfully accomplished in man.

In looking over the field of gunshot wounds of the cord, we find that the only hopeful cases are those of concussion. While there has been considerable increase in the knowledge of cord lesions during the war, it must be acknowledged that no advance has been made in their treatment.

Gunshot Fractures of the Femur are very serious injuries, attended with a very high mortality, especially when the damage is in the upper third, and as a consequence, arrangements were made at a comparatively early period of the war to have femur cases treated in the forward areas.

To classify gunshot fractures of the femur would be difficult, so various are the lesions found. In the worst type, the leg is blown off. As observed in the earlier part of the article, the fracture may be only partial if the missile has glanced off the bone, or the missile may be embedded without having produced a solution of continuity. As a rule, the fracture besides being comminuted is oblique. There is nothing typical about the skin wounds. They may both be small or the entrance small and exit large, or on rare occasions both may be large, so that it is impossible to say which was entrance and which exit. In some, large areas of skin and soft parts are blown away, and no opinion regarding the damage to the soft tissues can safely be drawn from an inspection of the entrance and exit wounds, for with both small there may be and often is, widespread destruction within. Added to the destructive force of the missile is that due to the splinters which themselves act as destructive agents in that they are scattered about by the force of the explosive, and if a piece of muscle some distance away from the track of the bullet be examined microscopically, one sees hemorrhagic areas showing the wide-spread affect of the trauma. In general, they are nearly all comminuted and the commonest type is probably that in which there are one or two larger pieces, together with many small ones bridging the gap.

While the diagnosis of the fracture presents no difficulty, the associated injuries are very important and must be most carefully looked for. First, attention should be directed to the nerves since they must be examined while the patient is conscious. Some idea may be ascertained in the case of through-and-through wounds by the position of the entrance and exit apertures, and it is well to remember that it is unnecessary for the metal fragment actually to touch the nerve to produce a complete paralysis; a fast traveling bullet traversing the neighboring tissues may produce a complete physiological block, and one must not be misled by a certain amount of numbness, since it is not unusual to find such in cases where the femoral artery has been pierced. If the man can even feebly flex and extend the toes, you may be assured that the great sciatic is intact. The anterior crural is more difficult to examine as movement of the patella would be difficult to elicit on account of the pain, but if the cu-

taneous supply be borne in mind a definite opinion should be arrived at.

The treatment of gunshot femurs is one of the most difficult in the whole range of warfare. The man is considerably shocked from the effect of his wound. Hemorrhage in many cases, if it does not cause rapid death, aggravates the shock. He may arrive at a field ambulance with a tourniquet on and his leg roughly splinted. Before being sent to the casualty clearing station, the tourniquet must be removed, and the vessels either tied or clamped. At this stage, too, attempts must be made to combat shock by means of hot drinks, hot water bottles, warm blankets, pituitary extract, morphine, and when feasible 20 oz. of saline, preferably into a vein. A most important point is the application of a splint at the earliest possible moment in order to minimize the shock. If possible, the splint should be applied at the first dressing station, and the war has most assuredly demonstrated that for transport purposes, there is nothing to equal a Thomas splint. It can be put on quickly without removing any clothing, and the boot serves as an excellent support

FIG. 3.—Fracture of the upper portion of the femur

for the extension. The ring must fit the upper part of the thigh snugly, and rests on the tuberosity of the ischium, and not upon the pubic arch. Provision, of course, is made to keep the lower end of the splint from touching the stretcher, and this is quickly accomplished by making a foot support of aluminum or a device can be quickly made to fit a stretcher. If not applied farther forward, such a splint should be put on in the field ambulance and transferred as quickly as possible to the casualty clearing station.

Previous to arrival at the C. C. S., while dressings had been applied to the wound, and superficial foreign matter removed, and hemorrhage controlled, no attempt at cleansing has been made. His field card accompanies him and contains notes of the probable extent of the injuries. If the man is very badly shocked, with blanched lips, rapid, feeble pulse, and cold extremities, provided there is no bleeding, the shock must be combatted before submitting him to operation. Blood transfusion is indicated if the shock has been due to loss of blood, etc. In the meantime, *x*-rays are made of the necessary areas. Having decided to operate, the man, still lying in the stretcher, is taken to the operating room and anesthetized. The splint is then removed, as well as the necessary clothing. The surrounding skin area is carefully sterilized, and attention is then directed to the wound. Provided the case is gotten before obvious signs of sepsis have set in, the wound or wounds are carefully excised, any skin or muscle being divided to allow of adequate exposure of the depth of the wound, and also any pockets. Arteries and important nerve trunks are the only things which must not be sacrificed, and every bit of possibly infected tissue should be removed. In these cases, one cannot, unfortunately, excise the area *en bloc*, on account of the fracture, but it should be done as far as possible. Needless to say, the metal must be removed. The question now arises, what is to be done with the loose pieces? The rule is to leave any moderately large fragment, provided it has any periosteal attachment. Those pieces which are wholly loose should be thrown away. Each case, however, must be judged on its merits. If a piece of clothing, for example, were lying among the fragments, they should all be removed, as they are in all probability already infected. The objection to taking away the loose pieces is that union may fail, for it has been shown that a comminuted fracture unites more readily than a transverse one. But in the opinion of most surgeons, the avoidance of sepsis is the first consideration. When there are one or two large fragments and many small, the latter are the ones directly hit by the missile, and are consequently the most dangerous. If a bruise can be identified upon any fragment, the area should be curetted at least. If the missile has simply knocked off a piece of the outer portion of the bone, it is safest to remove it. Where the bone has simply been bruised that area should be either scraped with a sharp curette, or removed with a burr. Having satisfied oneself that all infected material as well as all devitalized tissue has been removed, the question of closing the wound comes up. Experience here is more valuable than anything else. A similar wound of the arm or leg would in all probability do well with primary closure, but many surgeons are still afraid to suture gunshot fractures of the thigh. A *sine qua non* is to have a dry field, so that if oozing persists it should not be sutured. Another contraindication would be a cavity in a bone, for experience teaches that they are very prone to break down. If the hole is such as to be readily filled with living muscle, primary suture is then justifiable. Bone fissures are another determining factor. They are of two kinds, the open and the closed. The latter are not dangerous as they contain no blood clot, but the former very quickly allow infection to spread up the bone, so that unless gotten very early it is unwise to resort to primary suture. If one is sure of his technique and satisfied that every step has been thoroughly accomplished, provided all bleeding is controlled and he can keep his patient in hospital for a week or ten days, then closure should be adopted. If possible, through and through sutures of silkworm gut inserted some distance beneath the wound are best, and if there is much tension, they may be tied over rubber tubes. If

this plan is impossible, the wound is sutured in layers, and without drainage. Dry dressings and bandages are applied and the splint is again put on. On this occasion, adhesive strapping or gauze soaked in Sinclair's glue is used for extension.

At the operation, a culture is made from various parts of the wound. This is of considerable value in the after-treatment, since in cases of primary closure, if the growth shows a *Streptococcus hæmolyticus*, the wound should be opened up at once and provision made for ample drainage. Doubtless, after every excision a few organisms remain and the tissues are able to cope successfully with them, but against the hemolytic streptococcus they invariably fail. It is common for a rise in temperature for a day or two to follow primary suture, but the best indication as to the success of the operation is the appearance and well-being of the individual.

If, on the other hand, one has any doubt whatsoever about the sterility of the wound, what has been called delayed primary suture should be resorted to. The wound should be carefully packed with sterile gauze, covered with dressings, and bandaged. Oftentime, the gauze is impregnated with various antiseptics, as flavine 1-1000, or ether, but if the excision has been thoroughly done, sterile gauze should be sufficient. The man is then sent to the base, and, preferably on the second day, or about 48 hours after the primary operation, he is again anesthetized, the packing removed, and the wound sutured, unless there is evidence of suppuration. Except for the additional time required and the administering of a second anesthetic, the wound will heal just as promptly as at the original operation. Consequently, in the campaign of 1918, the fashionable procedure was undoubtedly delayed primary suture.

A complication which commonly affects gunshot fractures of the thigh is gas gangrene. In civil life it is of very infrequent occurrence, so that surgeons in general were quite unfamiliar with its symptomatology. Consequently, in the early days of the war, it was a dreaded complication and was responsible for many deaths. It occurs in two forms, the superficial and the deep. The former affects the subcutaneous tissues only, and, as a rule, is not very serious. The latter, on the other hand, is a terrible complication. The organisms responsible are anerobes, and thrive on dead tissue. Toward the end of the war, the opinion was gaining ground that the infection was primarily and mainly a disease of muscle; at any rate, it is now recognized in its earliest stage by the condition of the muscles. In the later stages, the blood-stained discharge has a characteristic offensive odor, and if gas is present it will show up very well under the *x*-ray. Instead of the normal purplish-brown color, the muscles involved are a brick red. Later they take on a yellowish green appearance, and are noncontractile, and may crepitate. In cases at all advanced, the skin is characteristic. There are blebs containing altered blood, and when the cuticle is removed a shiny purplish-red derma is exposed—a very serious symptom indeed, and usually demands amputation. Later still, the skin assumes a yellowish-green tint.

Suppose, then, that on excising a wound a group of muscles or a single muscle presents definite evidence of an early infection with gas gangrene, what course should one pursue? Provided there are no contraindications, the involved muscle should be excised in its entirety and the wound treated as for delayed primary suture. But every portion of dead tissue must, of course, be excised. Where the disease is at all advanced amputation should be performed at once.

Thus far, we have assumed that the thigh wounds have arrived at a reasonably early period. But naturally all cannot be brought to the Casualty Clearing Station at the most desirable time. What, then, is the treatment after the period for excision has passed. Under anesthesia, all foreign bodies and pieces of clothing are removed and attention given to the bleeding. Obvious dead tissue is cut away, and provision is made for free drainage. It is here that the multitudinous variety of antiseptics comes into use, and the choice will depend largely upon what is the most popular at the time. There is no doubt, however, that Kakin's solution, used by the Carrel method, was the most popular during the war. In brief, the method consists in placing one or more Carrel tubes (small rubber tubing with minute fenestræ) in every corner of the wound and gently packing the remainder of the wound with gauze. The tubes are all connected with a glass tube which in turn is joined to a bottle placed above the bed and containing the solution. Every two hours a stop-cock is released and the wound is saturated with the antiseptic. The wounds are dressed once daily, and smears are made from time to time, and the bacteria per field counted. When none or very few are found, the wound is ready for secondary suture, or suture when granulation tissue is well established. If but a small wound remains, it may be drawn together with adhesive, otherwise it will be necessary to give an anesthetic and suture the wound, making sure that no dead space remains.

So far, we have not considered cases where the question of amputation comes up. Good judgment, based on experience, is here a most valuable asset. To sacrifice a limb needlessly is a most regrettable affair, but is nothing compared with the loss of life caused by too great conservatism. Several factors must be taken into consideration. The age of the man would have a determining factor, since an elderly man would not have as good resistance against subsequent infection as a young man. If the limb is hopelessly mangled there would be no doubt whatever, but there are many borderland cases. On the other hand there are certain definite indications for a primary amputation. These are:

1. Great pulverization of the bone.

2. Certain cases where there has been very extensive loss of skin.

3. Rupture of the main blood vessels. This is in a case of fracture, in early cases, the most important factor of all. It was thought that owing to the pre-war experimental work that had been done on blood vessels, many opportunities would offer for suturing holes in the main arteries, and, therefore, prevent the occurrence of gangrene. But there are many difficulties. First was the small size of the main vessels, for instance in the thigh. Young men in fit physical condition have small

arteries. Then to be able to suture the rent the case must be gotten early. Later on the vessel becomes embedded and will not hold the sutures. So that while end-to-end and lateral sutures have been performed in a considerable number of instances, it is not proved to have been any better than ligature, and secondary hemorrhage is more liable to occur. The same may be said of Tuffier's tubes.

4. Where virulent sepsis is already established in extensive wounds, the patient being in a low condition.

5. Where the fracture is complicated by extensive comminution of the condyles.

6. The presence of well established gas gangrene. If only one group of muscles be involved, excision should be attempted, but if on account of the presence of important structures excision cannot be thoroughly done, amputation should be resorted to.

Another factor which would influence the decision would be the presence of severe nerve lesions. For example if the great sciatic be divided, unless one can be reasonably sure that union by at least delayed primary suture can be obtained, it is quite debatable whether it is worth while to save the limb, under the most favorable conditions with suture of the nerve in 48 hours and healing by first intention, it will be two or three years before function is restored, and if sepsis occurs the probability of getting a useful leg is slight.

As to the amputation itself, it depends upon the conditions found. Early in the war the guillotine method came into general use on account of the severe sepsis and gas gangrene. Towards the close, however, when surgeons depended for success upon early excision rather than antiseptics, circular or modified circular amputations were more and more practised and with excellent results.

Knee-joint.—A common complication of a fracture of the femur is involvement of the knee-joint. In over fifty per cent. of gunshot wounds of this joint there is an accompanying bone injury. Septic arthritis in the early days of the war was commonly treated by inserting drainage tubes in various ways, but practically all did badly and they were discarded, it having been realized that they were acting merely as foreign bodies. Very early there was instituted the practice of excising the wounds and sewing up the synovial membrane, and the results were so good, as compared with the previous experiences that it gave the impetus to the early excision of wounds in general.

There are various degrees of bone involvement. A bullet may drill a hole in the femur and penetrate the joint, and except for a moderate effusion, do no harm. In other cases, the bones are badly comminuted, the femoral vessels lacerated, and a portion of the internal popliteal nerve blown away. Such a case calls, of course, for primary amputation. Granted that the case is not one for primary amputation, what is the procedure? After the surrounding area is thoroughly cleansed and towels fixed by clips to the skin, the damaged joint is inspected. *X*-rays will have previously been made, and the position of any metal accurately localized. The track in the skin capsule and synovial membrane is excised en bloc, and if there are two openings, each is dealt with. The track in the bone is cleansed by means of the actual cautery or a sharp gouge or curette. The knee may have been flexed at the time of the injury so that to follow the track properly, the fact must be kept in mind. If a metal fragment is sticking within the bone, the surrounding piece of cartilage must be gouged away. The missile or foreign material must be removed under the eye so that ample room must be secured. Comminution of the bone does not necessarily demand amputation. Even though the greater part of a condyle is shattered, provided the operator feels confident in his ability to obtain primary union, the joint should be saved, for it is remarkable what a useful limb may result provided infection does not occur, and if the joint turns out to be very unstable, it can be treated later on when all danger of sepsis is past. For it is very generally conceded that to do a primary excision in these cases, is not to be considered.

FIG. 1.—Fracture involving the knee joint.

True, primary excision was advocated quite strenuously by several surgeons in 1916 and 1917, but the end results were not good and it was largely abandoned. In dealing with point injuries, it was found out that there is not so much danger of trouble arising from infection spreading from a splintered surface as from wounds of the soft parts. When all foreign matter has been removed the joint is flushed out, preferably with saline, and the wound in the synovial membrane closed. If there has been extensive loss of this structure, the suprapatellar pouch may be mobilized and utilized to close the opening. When that fails to close the gap it must be packed with gauze and allowed to heal by granulation. Some smear B.I.P. over the excised areas before suturing, and good results have ensued, but if the excision has been carefully done, it is not necessary

and tends to keep up an irritation. If any doubt exists as to the sterility of the soft parts, a drain may be left down to the capsule. The leg is then carefully dressed and put in a splint with most careful immobilization. He should not be moved for a week, and carefully watched. There will likely be some temperature and effusion following the operation, but if everything goes well these rapidly subside. Early transport is apt to set up a reaction in the joint, but with rest it will rapidly subside. But the war has demonstrated that the synovial membrane has quite remarkable powers of resisting infection and is, in fact, quite comparable to the peritoneum. For instance, it is not uncommon to find infection limited entirely to the anterior portion of the joint. It has been proved, too, that when the posterior part of the joint becomes involved, the spread is lateral by the extensions along the popliteus and semimembranosus. If, however, sepsis is definitely established there is nothing to do but freely open up the joint. But to drain the knee-joint efficiently is an impossible problem so far. Various methods have been tried out, but none are effectual. Sooner or later the capsule gives way and abscesses track up the thigh or down the leg, and the man becomes very ill. Some of these patients will run a septic temperature for months, with pus discharging from the joint and extra-articular abscesses, and finally get well with a stiff joint, and often a crooked leg on account of the sagging at the knee, due to the giving way of the ligaments. Others again have had to have their legs amputated after months of suffering. Each case of suppurative arthritis must be judged upon its merits, but when the primary excision operation has failed and well marked sepsis is established and at best recovery with an ankylosed knee is to be expected, amputation is the proper procedure.

Excision as a substitute for amputation is not desirable as the end results even if patient survives are bad. If enough bone is cut away to get efficient drainage, a flail joint is the result.

While one realizes that to sacrifice a limb is most regrettable, yet to throw away a life by too great conservatism is a calamity. Besides I am not so sure that a stiff leg has so many advantages over a modern artificial limb that a man should suffer for weeks or months and all the time running the risk of a virulent septicemia or a secondary hemorrhage. In the case of the upper limb, the case is vastly different, for it is a very poor arm, indeed, which is not infinitely superior to anything which can be attached.

Lastly, there is the question of plating in recent gunshot fractures. This has been recommended from time to time, but should not be done. To put a long metal plate into a possibly infected wound is a mistake and is certain to give rise to trouble. It is generally recognized that good alignment should be obtained at the earliest possible time and not wait until the inflammation in the soft parts has subsided. A thorough knowledge of the mechanics of splinting will overcome almost any difficulty, but if unable to get a satisfactory position it will be justifiable to use silver wire. This, on account of its size, causes a minimum amount of irritation and frequently the wound will close over it. If not, it can be removed after it has fulfilled its function.

There is another method which should be mentioned only to be condemned, and that is the plan of placing a skewer or calipers into the condyles or upper end of the tibia for extension purposes. Good results have been obtained, I admit, but there have been many failures. The same is true of applying extension to the tibia and fibula with a pull on the os calcis. Horrible suppurating bone lesions are commonly the result.

Hip Joint.—Since gunshot wounds of the knee joint are by far the most common of joint injuries, they are the ones that have attracted the most attention, but not infrequently the hip joint is involved in thigh wounds, and is a very serious complication indeed. In bad cases, part of the acetabulum is knocked off and the head of the bone is splintered and lying on the dorsum ilii, while in other instances the hip joint is perforated by splinters from the great trochanter. These are particularly difficult cases to treat. Conservatism should be practised,

Fig. 5.—Shell fragment in the knee joint.

since amputation has a high mortality and the difficulties of fitting a suitable leg are great. Wound excision should be practised, but obviously inspection of the deeper parts is usually impossible, so that there will always be a grave doubt as to the sterility of the wound. Here, in cases of a badly disorganized joint, excision has a place, and if infection is avoided a very useful limb may result. These are very difficult cases to splint adequately, as the ordinary Thomas splint cannot be used, since the ring comes over the wound. To my mind, the best way of putting such up is the plaster of Paris spica, fixing the pelvis and extending to the ankle with large window cut out and keeping the thigh abducted. While the French made more and more use of plaster as the war proceeded, the British, on the other hand, used very little of it, and I think largely because Sir Robert Jones condemned it on account of its becoming soiled. While it takes some time to put on, there is nothing which will give such

good fixation, and with care can be kept clean, especially if jaconet be carefully applied to the edges of the opening.

The Leg.—After what has been said of thigh injuries, fractures of the leg can be dismissed in a few words. Since there are three fair-sized arteries, gangrene is not so apt to result as in the case of the thigh. Then only one bone may be fractured, in which case there is little trouble from the alignment. Naturally, a fracture of the tibia is a great deal worse than one of the fibula, although fragments from the latter may work great havoc in some cases where the tibia is intact. The question of amputation here is not so serious as in the thigh, since an artificial limb fitted to a leg stump is very efficient indeed, so that upon no account should a man run a great risk of his life when amputation offers a sure cure. I am not advocating promiscuous amputations, by any means. Artificial arms and legs will have to be supplied to thousands of soldiers for the remainder of their lives, and they are expensive. But when one sees many of these cases occupying beds in the hospital with discharging sinuses, and years after being wounded, with more or less stiffened joints, in spite of massage, the impression is borne in that conservatism can easily be carried too far.

Cases in which there is considerable loss of tibia with an intact fibula present special consideration, in that there is a liability to non-union. The usual routine of excision, if seen early enough, would be carried out, and if successful the flesh wound may be healed in, say, a fortnight. But if at the end of the usual time one finds no union has occurred, what is to be done? If the *x*-ray shows evidence of callous formation bridging the gap, the leg should be put in plaster for a further period of six weeks, when union may be satisfactory. If no progress is made, then the case is one for an autogenous bone graft. But suppose that in the first instance the gunshot wound suppurated, and continued, as many of them do, to discharge for months. In such a case, if there is much separation between the ends of the fragment, probably the best procedure is immediate amputation. No bone graft operation can be done in such a patient for at least six months after the wound is healed. Very frequently these wounds heal, remain healed for weeks or months, and then spontaneously break down, so that grafting in gunshot fractures which have suppurated for a long period is a precarious procedure, and not infrequently fails because of latent bacteria in the tissues, and a long period must elapse before another grafting can be tried.

Foot.—In dealing with fractures of the foot, conservatism, provided the cases are seen at the proper time, should be practised. If the ankle joint is involved there is usually associated injury to the bones. If badly shattered, amputation would necessarily be performed, but if the injury is slight the joint should be treated on the lines already outlined. If the os calcis is extensively destroyed, the irreparably damaged bone is excised and treated conservatively. If new bone forms, the result will probably be good. If none is reproduced, the functional result will be bad, but can be attended to later on when all danger of infection is passed. This principle is applicable to so many of the gunshot injuries about the foot. Then, too, if infection ensues following a wound of the carpus, and a badly crippled foot after months of sepsis is to be expected, amputation can be performed. In treating foot cases there are certain general principles to be observed. As to the position of the ankle, under no circumstances must the foot for any length of time be allowed to drop, and this applies with equal emphasis to injuries of the leg proper. It was a common occurrence to see men with plantar flexed feet and so fixed that even under an anesthetic the right angle could not be obtained, and oftentimes when there had been no fracture anywhere. As to amputations, Syme's still holds the field, and a man with a double Syme's amputation may walk excellently well indeed. If excisions of individual tarsal bones is done, the sole must be preserved as free of scars as possible. Chopart's amputation does not, as a rule, give good results, owing to the tendo Achillis pulling up the calcaneum, while amputations through the front of the tarsus, provided there is plenty of skin to cover, give satisfactory results. It is not advisable to leave only one toe, even though it be the big one.

Fractures of both tibia and fibula low down present a difficult problem in the way of extension. The best method, in my opinion, is to have a notched wooden footpiece and attach it to the foot by means of ¾-inch flannel strips going over the dorsum, but not encircling the foot. These are fixed by means of Sinclair's glue. Traction is then made on the footpiece. This gives one perfect control of the foot, and can be kept on for weeks without irritation. Personally, I have never seen it blister, although that has been given as an objection.

Fractures of the pelvis are common. Those of the buttock are frequently associated with injury to the cecum and pelvic colon. They are dangerous on account of the danger of secondary hemorrhage, which is difficult to control, and usually necessitates opening the abdomen and trying the internal iliac. Fragments, too, are often driven into the iliacus muscle, and are hard to get away. Those of the rami are apt to have associated rectal, urethral, or bladder injuries, and are correspondingly serious. When a large, irregular fragment lodges among the sacral plexus there may be terrific pain, which persists until it is removed. All pelvic cases are preferably put up in a plaster spica with windows for the wounds. In many instances they really belong to the abdominal class of wounds.

Fractures of the Arm.—Fractures of the humerus are very common, and in general are treated on the lines already outlined. If the shoulder joint is involved, conservatism should be practised, since primary excision is very apt to be followed by a flail joint. Should the head be excised the arm should be put up, abducted to about 60°. Great care must be taken to test the nerves before operating on the humerus. The commonest involved is the musculospiral, and it should be examined before the patient leaves the table. Fractures near the elbow are common, and the lower fragment usually comes forward. When the elbow joint is involved excision should not be adopted except perhaps when there is involvement of the head of the radius, in which case the head should invariably be cut away. The best splint for transporting arm cases is the Thomas,

but when the base is reached it should be discarded and replaced by the Wilson splint. This is fixed to the chest by means of plaster, and no matter where the wound is it can be dressed without disturbing the fragments, and allows the patient to get about.

Fig. 6.—The Wilson splint for arm fracture.

When ankylosis is to be expected, the parts should be fixed at a right angle with the arm midway between pronation and supination. Where both bones of the forearm are fractured, the great difficulty, apart from combating sepsis, is the prevention of cross union. If the wound is low down it is often impossible to excise the wound completely on account of the numerous tendons. Any bony fragments which are projecting toward either bone should be removed, fearing cross union. No matter where the break, full supination is the best position to avoid such union, and in the subsequent manipulation it is always easier to recover pronation than supination.

Hand.—Ultraconservatism should govern one's treatment of the hand. If the best that can be expected of the wrist joint is ankylosis, the hand must be kept dorsiflexed, as the reverse position is a very weak hand indeed. As to extension in case of the forearm, a glove glued to the hand is excellent, and the same applies to a finger, the glue being applied to the distal end; or, if that is impossible, a hole may be bored in a nail and extension applied. When it is considered that about 50 per cent. of all wounds have some affection of the locomotor system or the usefulness of the arms, the importance of proper methods of treatment will be appreciated.

Fractures of the Mandible.—These have, to a large extent, become the property of the dental surgeon, who has made great advances in their treatment. Only a brief reference will be made to them. If there has been little or no loss of bone, the case is easily handled, a vulcanite splint being applied. But where there is, say, an inch of bone missing, the problem is more difficult. There are different ways of attacking the problem. Probably the best is that of the French school. The fractured ends are allowed to come together, and are fixed in position. After a time the parts are separated by about 1 mm., then again fixed. Later a further separation of 1 mm. is made, and so on until the mandible is reconstituted entire. The other plan is to keep the parts separated so that there is proper occlusion till the wounds are well healed and put in an autoplastic bone graft. Where bone grafting cannot be done, then a well-made denture must be permanently worn, and gives quite satisfactory results. Restoration of the natural size of the mandible is the ideal, but a deformed jaw with bony union is much to be preferred to one in which occlusion is correct but where the parts are not stable.

Fractures of the ribs and scapula occur with considerable frequency, but, as a rule, call for no special treatment in themselves. Oftentimes they are associated with lung or pleural complications, and are treated as such. Occasionally a piece of rib is shown by the *x*-ray to be embedded in the lung. In such instances, provided the parietal wound is of the sucking variety, with hemothorax, the procedure adopted toward the end of the war, and with marked success, was to enlarge the wound after

Fig. 7.—Shell fragments in the hand.

excising the infected area, mop out the blood, remove the foreign body, and suture the lung. When bleeding is controlled, and the pleural cavity is dry, the parietal wound is closed, using, if necessary, sliding flaps and without any drain.

MEDICAL RECORD.

OBLITERATION OF THE INFERIOR VENA CAVA.

THE evolution of an obliterative process of the inferior vena cava may be rapid, but generally it is slow. Usually preceded by the symptoms of the causal disease, obliteration of this vessel commences with edema, which continues to increase for a time and then becomes stationary, after which it diminishes when a collateral circulation has been established. If the patient should survive long enough the edema may almost completely disappear, but the superficial veins will remain greatly dilated. The patient then offers the aspect of a varicose case, the legs often covered with ulcers or at least presenting an eczematous condition of the integuments. In some cases life may be preserved for many years without too much suffering. But patients do not always support obliteration of the inferior vena cava with such ease, and numerous deaths occur either from the progress of the causal affection or because the myocardium is functionally insufficient to overcome this cause of interference to the circulation. Or a pulmonary embolus, asystoly, or uremia may close the scene. The prognosis consequently depends upon both the cause of the obliteration and its site, and the state of the heart. It likewise depends upon the rapidity with which the caval lesion is constituted, it being all the more serious the more quickly this takes place.

From its topography, the edema is rather characteristic. It cannot be mistaken for the soft cachectic edema limited to the declivous portions of the body. The likewise soft edema of asystolic patients will be recognized by examination of the heart. The edema of renal subjects will be far more likely to give rise to diagnostic difficulties. We do not refer to the fleeting edema of the interstitial nephritides, but to early and durable dropsy of the hydropigenous nephritides, which begins at the malleoli, extends up the lower limbs, and tends to terminate in anasarca. In the edema of nephritis pressure of the finger causes pitting, while in the case of obliteration of the inferior vena cava the impression imparted to the feel is that of a limb infiltrated with fat.

All things considered, the edema resulting from obliteration of the inferior vena cava is easy of recognition; it begins at the malleoli, invades the lower half of the body from below upward and is a hard edema. It is also easy to differentiate the collateral circulation of obliteration of the inferior vena cava from that arising in atrophic cirrhosis of the liver—excepting in those cases where obliteration exclusively involves the suprahepatic territory of the vena cava. The enormous bunches of varicose veins which extend from the groin up toward the thoracic region can only indicate an obliteration of the vena cava. It should also be noted that in this case the blood circulates from below upward, while in Laennec's cirrhosis the opposite is true, according to our old friend Sappey, whose teachings are still to be reckoned with, even in the present enlightened century.

THE PATHOLOGY OF DEMENTIA PRECOX.

DEMENTIA precox is usually characterized pathologically by neuroepithelial lesions of the brain. Macroscopical examinations, however, do not give constant results; occasionally a bilateral atrophy of the cerebral hemispheres is noted, but the atrophy may likewise involve only one side or it may be partial and limited to the frontal lobe. It has a predilection for the areas of association and respects those of projection to a great extent, occurring in them only in cases of long standing. The atrophic process is never accompanied by changes in the meninges or vascular system, and the pachymeningitis that has been encountered at autopsy of subjects who have lived to a certain age is the result of senescence. The atrophy of the cerebral or cerebellar hemispheres has nothing characteristic, as it is met with in the insane in general. Macroscopically, the cord appears normal in most cases, but there may be some anteroposterior flattening. The meninges are intact, while the cerebrospinal fluid offers nothing abnormal in aspect.

On the other hand, the microscopical lesions encountered are pathognomonic of dementia precox and are seated exclusively in the neuroepithelial tissue of the cerebral areas of association. The changes consist of a granulopigmentary degeneration with atrophy of the neuron, frequently with vacuolization of the protoplasm and destruction of its prolongations, dendrites, and axis-cylinders, all of which provoke cell autonomy and therefore are essential for the symptom dementia. The neuroglia proliferates in direct ratio to the atrophy of the neuron. In no case have lesions of the vessel walls (diapedesis, cell infiltration) been met with which could be attributed to the syndrome of dementia precox. Three types of lesion exist, namely, the preliminary lesions which are of congenital origin and most inconstant; the immediate lesions which occur at the phase of full development of the process, and lastly the consecutive lesions which mark the arrest of development of the neuron. The preliminary and consecutive lesions have only a rela-

tive importance from the viewpoint of pathology by reason of their origin. Etiologically and pathogenically they are of interest because on the one hand they reveal the influence of heredity while on the other they indicate the time at which the psychosis may have developed.

Alone, the immediate lesions are important pathologically as they occur at the stage of full development of the morbid process and are constant and identical in themselves. It may be objected that they are not peculiar to dementia precox, but it is a remarkable fact that these lesions alone exist in this morbid process without any vasculoconnective tissue changes. An elective property of the pathogenic element for the neuron cannot be admitted, this element being essentially variable, and it is more logical to suppose that at the origin of the lesions of the brain in dementia precox there is a special vulnerability of the neuron manifesting itself by a lessened organic resistance (meionexia), ending in the bankruptcy of the nerve cell under the influence of some pathogenic factor whose action is not sufficiently intense to provoke a toxiinjectious psychosis. The meionexia of the neuron may be due either to a neuropsychopathic heredity, especially cerebral, or to the action of some pathogenic factor arising during the previous existence of the patient. Therefore the lesions of dementia precox are changes having an accidental origin.

The influence of heredity is here reduced to its simplest expression. Heredity of toxic or infectious processes in the ascendant provokes degeneration and not dementia precox, which is a primary psychosis forming an entity and not a *finale*. If, on the other hand, this psychosis appears to end in a confusional state it is in reality a dementia precox with a dramatic clinical début, clinical only because the initial stage of the disease already dates far back into the past, the first early symptoms having generally passed by unnoticed. Much has been said regarding the morbid agents which may give rise to this psychopathy, but it is probably logical to admit that the lesions of dementia precox are provoked by an autointoxication of sexual, gastrointestinal, hepatic, or other origin—in other words, an endogenous factor acting upon an organically enfeebled neuron.

THE TREATMENT OF SENILE OSTEOMALACIA.

SENILE osteomalacia is a process characterized clinically by pain and deformity of the bones, involving the thorax and spine more particularly, but occasionally extending to the pelvis and limbs. Necropsy reveals bends in the bones, with or without fracture. The bones are soft, spongy, and friable, and crush easily under pressure of the finger. The bone marrow is in a state of reaction. Chemical analysis shows decalcification, especially evident in those portions of the skeleton which are the seat of the more advanced pathological process. There is also a hypercalcification of the tissues, especially of those the nutrition of which is lowered, such as the cardiovascular system. There is an excess in elimination of calcium by the feces.

It is possible to produce osteomalacia experimentally in rabbits by injections of adrenalin and administration of calcium chloride. The resulting disturbances are analogous to those met with in senile osteomalacia, namely, an excessive elimination of calcium in the stools, bone disassimilation of lime, and atheroma, from which it is fair to assume the pathogenesis of senile osteomalacia is very similar to the experimental form of the process. In both instances the evolution of the affection is the same. The causes of senile osteomalacia have not been explained either clinically or experimentally, so that the therapeutic indications are, to say the least, vague. However, an attempt should be made to stay the progress of the affection, if not to cure it.

A hygienic treatment is particularly indicated, and if this process should prove to be infectious, as some Italian observers are inclined to suspect, the patients should be isolated. By a rational alimentation the digestive tract will be relieved of some of its work, thereby improving the general nutrition. The food should be rich in phosphates and mineral salts, such as eggs, milk, and cereals. By an appropriate medication the calcium disassimilation may be arrested to a certain extent. From this viewpoint, phosphorus seems indicated in the form of phosphorated cod-liver oil or the phosphates of calcium, to which may be added iron and cinchona; but these drugs are uncertain expedients upon which too much reliance must not be placed. Besnard, Bossi, and some other writers are partisans of treatment with adrenalin, and in this respect it is interesting to note that Dauplais (Thesis, Nancy, 1911) obtained exactly the opposite phenomenon with this drug, namely, decalcification, and he very justly remarks that in the cases reported by both Besnard and Bossi adrenalin did not act upon the osteopathic process, but rather it controlled certain causes of the affection. It is unquestionable that the exhibition of adrenalin has met with signal failure in most cases.

THE ANATOMICAL EVOLUTION OF DUODENAL ULCER.

THERE are several possible anatomical evolutions for ulcer of the duodenum. In the first place, the lesion may extend in surface and in some cases this takes place following the axis of the gut, often attaining the pylorus when the ulcer is near it, or even penetrating the stomach itself. Such an extension may result in the confluence of other neighboring ulcers if they exist, in which case the lesion assumes an irregular, polycyclical type. But the ulcer may also extend in a direction perpendicular to the axis of the duodenum, thus taking on an annular form. In this case, also, this disposition may be the result of confluence of several ulcers lying in proximity to each other; such instances have been recorded by Mennier, Codman, and other observers.

Finally, the evolution of the lesion may take place in depth, and in reality often does so, ending in perforation of the duodenum either into the peritoneal cavity, a neighboring hollow viscus, or a blood-vessel.

That cicatrization of duodenal ulcer is not uncommon is now a recognized fact. According to the phase of the process, as well as the rapidity of evolution and importance of the inflammatory phenomena which accompany the ulcer—and which will also leave their traces—various types of cicatrices will be found. In some instances the lesions will be reduced to a minimum, so that in fact nothing can be seen macroscopically on either the mucosa or peritoneum. It may even require a very attentive microscopic examination in order to detect evidences of cicatrical formation. The peritoneum will be found histologically normal, the mucosa appears healthy, its epithelium and glands have regenerated and offer an absolutely normal aspect, and it is only in the muscular stratum that the cicatricial fibrous foci are discovered, the only remaining vestige of the former ulcerative process. Usually, however, the ulcer leaves a visible cicatrix on the duodenal mucosa and peritoneum, varying in extent. It may remain limited or extend over the peritoneal surface on the areas where the serosa has been the seat of inflammation, producing the formation of small adhesions on the duodenal peritoneum. These adhesions are retractile, pucker the surface of the viscus, and thus produce a diminution of its lumen. Finally, the cicatrix may be extensive, thick, and solid, forming a hard, callous mass, comprising a more or less considerable extent of the duodenum, thus reducing the caliber of its lumen.

The vascular lesions in the neighborhood of a duodenal ulcer are rather frequent. The intimate relationship of the pancreatico-duodenal artery and the first portion of the duodenum and the disposal in a double arch of its branches at the level of the second portion of the viscus explain the frequency of the lesions. By extending in depth the ulcer reaches this vessel and erodes its walls, leaving a gaping opening with indurated edges without tendency to retract.

Lesions of the gastroepiploic, mesenteric, and hepatic arteries have been recorded, likewise of the portal vein, but in the case of the latter vessel it may merely become pressed and the seat of thrombosis. Finally, several instances have been reported of acute aneurysm of the abdominal aorta in contact with a retropancreatic pus focus due to an ulcer of the fourth portion of the duodenum.

CONGENITAL CYSTS ON THE SIDE OF THE NECK.

Congenital cysts situated in the lateral region of the neck comprise tumors of divers anatomical types, which may be conveniently classified as follows: (1) unilocular cysts—dermoids, mucoids, and epitheliolymphoids; (2) multilocular cysts—congenital serous cysts, the so-called branchiogenous cysts, and parathyroid cysts. The pathogenesis of all these types is as yet poorly, if at all, understood. The branchial theory, still in vogue, supposes that these products are derived from the remains of the branchial apparatus, especially the dermoid, mucoid, epitheliolymphoid, and the so-called branchiogenous cysts. Besides this preponderating group of branchiogenous cysts, the existence of cysts having a lymphatic origin was at one time admitted (congenital serous cyst or cystic lymphangioma), and also parathyroid cysts. At present the branchial theory no longer prevails to the same extent as formerly. With recent researches, the great majority of so-called branchiogenous products are regarded as mixed tumors having no relation to branchial formations. The latter play only a subordinate part in the formation of the neck, and on the other hand the congenital cysts—including serous cysts—offer a close relationship with the mixed growths of other viscera.

From the clinical viewpoint these growths usually appear either at birth or in early childhood. They are manifest in the form of fluid tumors developing in the lateral region of the neck. The functional symptoms to which they give rise result from their anatomical relationship with the divers organs of the region without belonging properly to them. Congenital serous cysts are unquestionably the most interesting from the clinical standpoint. The progress of these morbid congenital products is essentially slow and progressive.

The diagnosis of these cysts reposes upon objective findings, the evolution of the process, and occasionally the results of an exploratory puncture. The differential diagnosis is to be made with all types of neoplasm situated in the lateral region of the neck. Congenital cysts are to be carefully separated from mixed neoplasms of the parotid gland and branchiogenous epitheliomata, the rapid and malignant evolution of which is quite different from that of the former class of growths. Anatomical diagnosis is made by histological examination of the structures removed at operation. Regardless of the usual benignity of these neoplasms a complete operative removal is recommended in most instances, and should be undertaken during the second year of life, but not before.

Gonorrheal Keratosis.

The history of the first recorded case of this affection is of interest. It was treated by E. Vidal as a syphilitic lesion. As treatment was negative the case passed under the care of Besnier and Brocq, the latter being in charge. The diagnosis was a trophic affection and the condition was treated by cautery over the spine. Finally the case came under the care of Jacquet. This was in 1890. Jacquet noted that the patient had gonorrheal rheumatism, and boldly made the diagnosis of a medullary irritation due to the gonococcus. Under hydrotherapy the patient made a prompt and complete recovery.

Two years later the patient suffered a general relapse and came into the hands of Vidal again, who, profiting by the experience of Jacquet, published the case as one of gonorrheal keratosis and arthritis. Since that period a number of similar cases have been reported, including true cutaneous horns. At present about 40 are on record. In the *Annales de dermatologie* for May, 1919, Trémolières analyzes the material. These cases are seldom seen save in severe and complicated gonorrhea. While the lesions may appear almost anywhere on the surface the region of predilection is the soles of the feet, between the toes, and about the nails. Unlike ordinary corns, etc., they give little trouble. The microscope shows the condition to be in reality a parakeratosis. The pathogenesis is still obscure and no one has surely demonstrated the presence of the gonococcus in the lesions. Lumbar puncture when practised has shown a healthy fluid. The trophoneurotic theory has not been proven, but elements are often present which combine to render the nutrition of the feet defective, such as arthritis in the lower extremities.

Fistulæ on the Dorsum Penis.

Ehrenpreis reports in the *Journal d'urologie* for May a case of what was clearly a congenital fistula of the dorsum penis. While the patient was a soldier there was no history of injury or gonorrhea nor in fact was there any history whatever which bore on such a lesion. The patient had been aware of its existence for years and it had never caused him any annoyance, although at times there was a purulent discharge for which he had finally sought advice. Examination in the lad of 21 showed quite normal male genitals save for feminine configuration of the pubic hair. Near the central end of the shaft of the penis there was a break in the skin, a fold running transversely, which admitted a probe and allowed the escape of a little seropus. Another furrow ran in an anteroposterior direction in the balanopreputial groove, and the two malformations were evidently associated genetically. The central malformation showed that a urethral mucosa lined the fistulous tract. On the other hand there was a defect of the prepuce at the site of the anteroposterior furrow in the sulcus. The sites of both malformations were extirpated and the microscope showed a marked similarity in the texture of the walls of the fistulæ which were lined with epithelium resembling that of the normal posterior urethra. The author has been unable to look up other cases or to attempt an embryological explanation of the condition. He, however, suggests the opinion that the condition was one of duplex urethra, masked by accidental circumstances.

Rehabilitation of Devastated France.

As is known, this campaign will be initiated by the Interallied Congress for Social Hygiene for the Reconstruction of the Regions of France Devastated by the War. Vitoux in *La Presse Médicale* for May 12 states that the real aim of the society is more extensive and will overflow into a social hygiene of intact France. The first problem in importance is drinking water and this certainly concerns the whole of France; but in the devasted regions the problem is more difficult, for in consequence of the inhuman acts of the Germans in poisoning wells, the water must be actually disinfected by some such process as ozonization or javellization. Liquid chlorine also has its advocates. Boiling water in small quantities, the sinking of artesian wells and all the older resources should be used. The universal object is sterile or sterilized water, and to the amount of 100 liters per head per day. Next in order comes the purification of the soil, both superficial and deep. The first step is the mechanical removal of all surface debris. In many places the surface has been inundated because water has collected in shell holes, mines, etc., and the original terrain has been transformed to marshland. In these localities malaria becomes a menace, and the watchword is drainage by ditching and canalization. As side activities may be mentioned disinfection of the exposed surfaces and a campaign against insect life. Certain spots require special attention, as old latrines, dung-heaps, stables, slaughter houses, and the like. No general law can be laid down concerning purification of the deep soil, which naturally takes cognizance of dugouts, subterranean passages, and the like. These steps are merely the initial activities toward rehabilitation.

Septicemic Form of Sporotrichosis.

The evolution of our knowledge of sporotrichosis is progressing rapidly and numerous clinical reports are appearing on various phases of the disease-group. Last April Lesné reported before the Société de Pediatrie of Paris (*La Presse Médicale*, April 28, 1919) an account of a case of sporotrichosis in a child aged four. Early in November, 1918, a lesion appeared in the right medius, which was followed by similar ones on the ring and little fingers. The general condition remained excellent. The lesions are described as "gatherings," and, as the first one evidently contained fluid, it was incised and the pus cultivated with negative result. Eight days later an ulcer appeared at the tip of the tongue, with submaxillary adenopathy. From the clinical ensemble and result of laboratory examination a mycosis was diagnosticated. From pus from the ring finger cultures of a sporotrichum were obtained, while sporoagglutination was positive. Gummata later appeared, especially about the cubital region. The iodine treatment produced a notable amelioration, but by the end of December the child presented evidences of an endocranial location—intense headache, vomiting, fever, slow pulse, but no meningeal reaction. Iodine exerted no favorable influence on the brain and attacks of Jacksonian epilepsy preceded the fatal termination. Unfortunately, no autopsy could be obtained, although the term septicemia is believed to have been justified by the clinical and laboratory finds.

Simulation of Urinary Affections by Soldiers.

As human nature was repeatedly shown up during the world war, it may interest us to learn that simulators did a thriving business in counterfeiting such functional affections as polyuria, pollakiuria, oliguria, and less obvious affections of the urinary

and pelvic organs. Escat in the *Journal d'Urologie* for May refers to a material of 3,000 patients with urogenital affections of which number but seven were caught in deliberate simulation. The great number of "pseudourinary" subjects were evidently not simulators. The nervous man is naturally beset with affections like polyuria and pollakiuria and at times with pseudoretention. The latter phenomenon is puzzling because it is often shortlived or subsides quickly under simple treatment. In speaking of retention, the author mentions that, in order to detect the simulator, the neurologist and chemist may have to be called in. The author dwells at some length on feigned hematuria, produced by the use of aniline dyes. This is readily unmasked by washing out the bladder at regular intervals, when the urine in the normal case soon comes away clear.

News of the Week.

Professional Guild Organized Against Health Insurance.—Through the presidents and secretaries of their organization, the Medical, Dental, and Pharmaceutical Societies of Kings County have formed a guild known as the Professional Guild of Kings County which has for its object the presentation of a scientific plan for welding of doctors, dentists, and pharmacists of the State of New York into a "compact working unit with the moral courage to oppose such pernicious legislation as that embodied in the Davenport-Donahue bill providing from compulsory health insurance. The specific purposes of the organization are: (1) Unification of the professions. (2) The formulation of legislation especially along lines of public health. (3) The education of the public in matters of public health legislation and cooperation with other civic bodies along lines of public improvement. The plan contemplates the establishment of a similar organization in New York County and then the extension of the organization to the various county medical, dental, and pharmaceutical societies.

Cholera in Formosa.—More than two hundred cases of cholera are said to have been found on the island of Formosa. A despatch from Tokio states that Japan has declared a quarantine against the island.

Americans Aid Poland.—A one-hundred bed memorial ward has been presented to the Warsaw University Clinic at the Child Jesus Hospital as a permanent contribution by the American people to the educational and health welfare of free Poland. This gift has been made through the American Red Cross and includes linen and a supply of rubber goods and drugs.

Opposed to Heroine.—The American Association of Pharmaceutical Chemists recently in session in Atlantic City passed resolutions asserting that the need of heroine for medicinal purposes is negligible in comparison with its evil effects as a habit-forming drug and recommending that its manufacture, sale, and distribution be prohibited by States and municipalities.

Newark Reports Decrease in Infant Mortality.—Newark, according to information given in a report issued by its Bureau of Child Hygiene, is the healthiest large city in the country for babies. During the first six months of 1919, the infant mortality rate of Newark has been 77.1 per thousand living births. St. Louis ranks second, with a rate of 84.2, and New York third, with a rate of 87.2. Newark's infant death rate in 1910 was 123 per thousand. The reduction is attributed entirely to the work in child hygiene. Dr. Julius Levy, head of the Bureau of Child Hygiene of that city, in commenting on the report, says that Newark is not free from any problem with which other cities of its class have to deal. Fifty per cent. of its population is foreign and fifty per cent. of the children are delivered by midwives.

Hospital Faces Deficit.—The board of governors of the Broad Street Hospital, New York, has issued its first annual report which shows that such an institution is greatly needed at the southern end of Manhattan Island. The hospital was opened in September, 1917, and during its first year cared for 1,334 patients, giving 18,101 days treatment in addition to 9,234 dispensary treatments. During this period it has responded to 1,813 ambulance calls. The financial statement included in the report showed that there is a deficit of $18,480 for the year.

Dr. David Felberbaum has removed his office to 58 West Fifty-eighth Street, New York City.

Red Cross Workers Honored.—According to word received from the Red Cross headquarters at Belgrade, a number of Red Cross workers have been decorated by Prince Alexander of Serbia. Major F. L. Emerson of New York and Dr. Regina Flood Keyes of Buffalo received the Order of the White Eagle, the former in recognition of his work at Belgrade and the latter for service in establishing and maintaining a hospital at Monastir. Dr. Francis M. Flood of Elmira received the Order of St. Sava.

Dr. S. Josephine Baker, Director of the Bureau of Child Hygiene of the New York City Department of Health, has been appointed a member of the Advisory Committee of the Federal Children's Bureau at Washington, and as such has been designated a special agent of the Children's Bureau in New York City.

Dr. Lucius P. Brown, Director of the Department of Food and Drugs of the New York Department of Health, who has been serving as a captain in the Medical Corps during the period of the war, has been discharged from the army and has resumed the duties of his office in the Health Department.

A Court Decision Under the Harrison Law.—An interesting court decision, relative to the enforcement of the Harrison act, is quoted in the Public Health Reports of July 18, 1919, in the case of Foreman v. United States. In this case a physician had been indicted and tried upon the charge of unlawfully dispensing, distributing, and selling morphine. The proof showed that what he had done was to issue prescriptions for morphine and cocaine to addicts, to gratify their craving for the drugs, and not for the purpose of cure. These prescriptions were filled by different druggists, the physician not acting in concert with any of the druggists, and not knowing where the prescriptions were to be taken to be filled. Under these circumstances the Circuit Court of Appeals of the Fourth Circuit held that the physician had

not made a sale of the drugs, nor had he done such a dispensing or distribution as would amount to a sale and that he, therefore, could not be convicted under the indictment. The Health Commissioner of New York City does not approve of this decision, and thinks it has no bearing upon the practice of physicians in this city.

Observations on Drug Addicts.—The New York City Health Department has made public the results of observations made on 2,776 drug users, which is about one-half of the number who have registered at the Board of Health's station for the registration of drug addicts. The Health Commissioner calls attention to several points brought out by these records. First, the occupations given by the drug users show that some part of each day the lives of others are at least indirectly in the care of secret users of drugs. The other outstanding fact is that the number registered, only five per cent. of the total number of addicts in this city, would tend to prove that the bootlegger is still busy and that there are many illegitimate channels open through which drugs are flowing undetected to the victims. Among the list of addicts investigated twenty-seven countries were represented, but the greater number, 2,621, claimed the United States as their birthplace. The next largest number came from Italy. Of those questioned at the clinic, 1,223 said they became drug victims through evil associations, 280 because of illness, 128 to relieve pain, 72 because of insomnia, 7 were led to drugs through taking alcoholic drink, and 50 through opium smoking, 12 because of family trouble, 3 were down and out, and 30 for the pleasure they got out of it.

Drug Traffic Ends in Newark.—Newark, N. J., which for years has been a distributing point of narcotics for addicts from surrounding cities, is said, by the International Revenue Department, to be absolutely clean of the traffic. The department figures show that between July 1, 1918, and July 1, 1919, 16,000 drug prescriptions were written and filled in Newark, calling for 381,679 grains of cocaine, morphine, and heroine. Addicts paid about $20,000 for this amount, which is exclusive of that paid to street peddlers.

New York's Oldest Resident Dies.—Mrs. Samantha Miller, believed to be at the time of her death the oldest living person in the State of New York, died at her home in Naples, N. Y., on August 17, at the age of 109 years. She was born January 5, 1810, in Herkimer County, and was the daughter of a Revolutionary soldier who was a member of Washington's body-guard.

Sea View Hospital to Be Kept for the Tuberculous.—Moved by the threat of injunction proceedings by civic organizations of Staten Island if he persisted in his plan to treat drug addicts at Sea View Hospital, Health Commissioner Royal S. Copeland has decided not to disturb the tuberculous inmates of this institution and will treat his addicts at Riverside Hospital on North Brother Island. There are 700 beds available there for drug addicts under treatment by Dr. Copeland, all the other patients in the hospital having been removed.

Protection Against Anthrax.—The necessity for greater vigilance in protecting the public against anthrax is one of the results of the war. During the war the Laboratory Division of the Surgeon General's office received reports of the occurrence of anthrax among soldiers and steps were taken to seek out the source of infection and remove the cause. It was found that the infection was undoubtedly due to shaving brushes purchased in open market. As a result of this discovery the United States Public Health Service notified local health authorities that brushes found in the market which did not bear the name or trade mark of the manufacturer should be regarded with suspicion and should be returned to the source from which they were secured, or should be disinfected.

Army Needs Men for Medical Corps.—A campaign is being conducted by the Army Recruiting Service to build up the Medical Corps to the strength required for efficient service in the field, and to care for wounded veterans still in the hospitals. Recruiting headquarters are at 461 Eighth Avenue, from which an intensive enlistment campaign will be carried on in the metropolitan district. The period of enlistment is for one year, and recruits will be assigned to duty at hospitals near New York.

Free Dental Clinic for Children.—The New York Association for Improving the Condition of the Poor has started a free dental clinic in the Italian Day School of the Children's Aid Society at 154 Hester Street, Manhattan, where a large room has been loaned and equipped modernly for this work. The plan is to afford free dental treatment to children of school and pre-school age among the residents of the Italian section of Manhattan between Broadway and the Bowery, from Canal to Houston Streets. Dr. Dwight R. Wilson has been instrumental in starting the clinic, which will be open for the present, Monday, Wednesday, and Friday mornings.

Jacobi Memorial Plans Expanded.—A few weeks ago it was announced that plans were being developed for the erection of a hospital in the Washington Heights section of New York as a memorial to the late Dr. Abraham Jacobi. This plan has been altered somewhat and it is now announced that appeals for contributions to a $1,000,000 fund will be made to the 140,000 physicians in the United States by the executive committee from its headquarters at 3785 Broadway. It is now planned to make the memorial for children only, to erect an annex to the Jewish Memorial Hospital, and to endow as many free beds in the hospital as possible as a tribute to Dr. Jacobi's work among the poor of this city.

The International Conference of Women Physicians, which will hold its opening meeting in New York September 15 and will continue for six weeks, announces its tentative program. "The Woman Physician and the Health of Women" will be the first general topic for discussion. Other subjects announced are: "Present Social Conditions and Their Effect on Health" and "The Psychological Aspects of the Sex Question, and Legislative Measures as they Reflect the Present Status of Sex Morality." The final week of the conference will be devoted to a more general discussion of these questions and representative non-medical women of the country will be invited to participate. The purpose of the conference is to reach a common ground of understanding upon which may

be the best methods for cooperation in dealing with social problems affecting the women of the world.

Nurses on a Hunger Strike.—Ninety-five student nurses in the Kings County Hospital Training School were recently in revolt against the food supplied to them by the city, saying that it was unfit for human consumption. They complained that the food was not only dirty and poorly cooked but was insufficient in quantity. The hospital authorities denied that there was any foundation for the complaints. The nurses continued to perform their regular duties, and soon returned to the hospital table under promise of good treatment.

Charitable Bequests.—The will of the late Dr. John Henry Thompson of New York makes a bequest of $1,000 to the Society for the Improvement of the Condition of the Poor of New York and a similar sum to the Orphan Children's Home at Utica, N. Y.

By the will of the late Emma J. Lesem of Philadelphia, bequests are made to the Jewish Hospital Association of Philadelphia and the Philadelphia Jewish Sanitarium for Consumptives.

The will of Henry S. Mace of New York City, makes bequests of $5,000 each to the Presbyterian and St. Luke's Hospitals.

The National Society for the Promotion of Occupational Therapy will hold its third annual meeting at Bowen Hall, Chicago, September 8-11, 1919.

Obituary Notes.—Dr. HENRIETTA M. THOMAS of Baltimore died in York, England, on August 4, of heart trouble, aged 40 years. She was a graduate of the Baltimore Medical College in 1904, and was formerly connected with the Thomas Wilson Sanatorium for Children at Mount Wilson, Baltimore County.

Dr. ELI EDWIN GRAVES, a graduate of the University of Vermont College of Medicine, in 1868, died at his home in Concord, N. H., on August 6, aged 72 years.

Dr. PEDRO FRANCKE of Havana, Cuba, who had been serving as house surgeon at the Bangor, Me., Hospital, died in Boston on August 19, aged 33 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 29, 1919.

American Hospital for London.—An important event, so far as American and British medicine is concerned, has occurred recently in London. It has long been felt that London does not hold the place in post-graduate medical instruction to which its wealth of clinical material justly entitles it. A movement to remedy this state of affairs has been considered for some little time. Under the auspices of the Royal Society of Medicine and under the immediate direction of Mr. Philip Franklin, an American surgeon long resident in London, with the assistance of many of the best known British physicians and surgeons, among whom may be particularly mentioned Sir Arbuthnot Lane, a meeting was held in the Council Chamber of the Royal Society of Medicine on Thursday, July 17, to approve and adopt a scheme for the foundation of the American hospital in London. The meeting was largely attended. Lord Reading opened the proceedings by an eloquent address and in the absence of the American Ambassador, Mr. R. Newton Crane moved the following resolution: "In commemoration of the cooperation of the medical men of the United States and Great Britain during the European war, and to strengthen the friendship existing between the two nations, the American hospital for Great Britain be and is hereby founded for the medical and surgical treatment of patients of all classes, irrespective of creed or nationality, and for the promotion of scientific study and research." Sir Arbuthnot Lane seconded, and the resolution was carried unanimously. The object of this hospital was excellently stated by Mr. Philip Franklin in a report presented to the meeting. He pointed out that although there are a few scattered beds in several of the London hospitals specially endowed for the use of American citizens, it is felt that these are not enough. There is no hospital in London conducted after the American system, where the American in Great Britain can be cared for after the manner of his own land. The hospital will supply this deficiency in every respect. There are other and valid reasons why a purely American hospital should be established in London, one of which is that it will aid in cementing the friendships formed by American and British medical men at the front and in England itself. Perhaps, however, by no means the least important reason why such an institution should be founded is that it will afford the opportunities for American medical men to avail themselves of the almost boundless material for post-graduate training which exists in the city by the Thames. Up to the present time when Americans have come to London and specialized in advanced medical study and research London has not formed one of their centers. The medical schools of Berlin, Vienna, and other German cities attracted the majority of Americans, largely because the teaching facilities of London were not organized and because the Germans employed all their wiles to draw foreigners and especially Americans to their medical schools, as much for political as for scientific purposes. In the future, London will be fully organized with regard to post-graduate instruction, if the existing portents come to pass, and taking into consideration the fact that English is the common tongue and that the war has brought about abundant good feeling between the two great nations of the English speaking races there is little doubt that Americans in search of European post-graduate medical teaching will flock to London. The American hospital will not only serve as headquarters, as a club indeed, but as their medical home. It may be added that the building of the institution will be erected on a convenient and appropriate site in the west end of London. It will be of the most recent and approved type, will contain free wards and pay wards, laboratories, a library, meeting room, and conversation room. Two medical committees, one for Great Britain and one for the United States

were constituted. The medical committee for Great Britain is composed of Sir William Osler, Sir Arbuthnot Lane, Sir Humphrey Rolleston, Sir John Bland Sutton, Mr. MacAlister, and Mr. Philip Franklin, with power to add to their number. The medical committee of the United States consists of Drs. George W. Crile, W. J. Mayo, Albert T. Ochsner, and Rudolph Matas, with power to add to their number.

Medical Domesday Book.—The Insurance Acts Committee of the British Medical Association held a meeting in London on July 25. Dr. H. W. Brackenbury, chairman of the committee, in referring to the question of keeping a record of cases, said it was hoped to have a continuous record of patients. There were at present records of a good many children, in connection with maternity centers, almost from their births. It was hoped that in the future these records would be passed on to the local medical authorities and the medical records of individual children continued through their school career up to the age of 16, or perhaps 18. The records should then pass into the hands of the medical practitioners under whose care these persons came, and the medical man would be expected to keep a proper record, which would remain in his possession until the patient passed out of his hands. The practitioner would then pass the documents over to the central authority of the Ministry of Health. In that way a record would be kept of some millions of individual lives from beginning to end and the records would be much more useful than any which had been kept in the past.

A Trade Union for Medical Men.—At the same meeting the question was discussed as to whether doctors should join a trade union. The suggestion was made some time ago that in order to defend their interests, members of the medical profession should follow the example of the trades and a form a union. It was recommended at this meeting that the British Medical Association should not endeavor to prevent members from joining any other body which was attempting to combine the profession on trade union lines. Dr. E. K. Fleming in moving the resolution urged that the policy of the British Medical Association should be one of cooperation with the Medico-Political Union. That was a question of policy. Personally he was not a believer in trade unionism in the profession, but they ought not to put "the lid" on those who wished to join the other body. Dr. C. H. Panting said he thought the Association was justified in fighting trade unionism tooth and nail. The resolution was defeated by 75 votes to 17. Although the British Medical Association, or rather the majority of its members, appears to be opposed to a medical union, the movement in its favor is the straw which shows which way the wind blows. It may be unethical and undignified for the medical profession to copy the methods of the trades for its own protection, but at the same time if its interests demand that such a step should be taken, some sacrifice of dignity and ethics must be made. Also it must be borne in mind that to a large extent, the old order of things is passing. The practice of medicine is going through a stage of transition and many of the old traditions will be cast on the scrap heap. However, it is well that a sane spirit of conservatism should still pervade the medical profession, and that while change and reforms are certain to come, its motto should be Festina lente.

Obituary.—A well known British medical writer has passed away, recently in the person of Dr. William Hall Peile. He was educated at Harrow School, Trinity College, Cambridge, and University College, London. He practised in the West End of London at Cotswold Sanatorium and at Sidmouth, Devon. He suffered from pulmonary tuberculosis and fell a victim to that disease at the age of fifty. Dr. Peile was an able and delightful writer and contributed during the last few years of his life, several articles on health subjects to the prominent British medical journals.

Progress of Medical Science.

5. Mechanical and Physiological Considerations in Tonsillectomy.—H. C. Masland bases this paper upon the dogmatic premise that though we have not learned the functions of the tonsil, its position at the gateway of the respiratory and digestive system is to enable it to perform a useful purpose. One could readily draw the conclusion from the statements made by certain dogmatists that its only function in the organism is to invite disease. Observing the primary developmental changes of the tonsil in the early years of life, it may be noted, in connection with the lingual tonsil and the nasopharyngeal adenoids, this ring of lymphatic structure is always of considerable size. It later undergoes regressive change, but there remains always some lymphatic structure throughout the ring. This suggests to the writer the possible interrelation, either or both interactivation and interinhibition, between this structure and the thymus and the thyroid in the early years of life particularly. How far this has been investigated he does not say, but he thinks that we cannot deny that this pharyngeal lymphatic ring, over which pass all ingested liquid, solid, or gaseous materials, does perform a vital function in the body. Kenyon gives 5 per cent. as the proportion of patients who show practically no deformities of the pillars and soft palate. Other statistics offer as low as 2 per cent. The writer is of the opinion that this latter estimate is more nearly correct. The human throat, he says, must be recognized as a marvellously organized structure to provide for nasal and oral respiration, deglutition, and the wide range of tone production of which it is capable. The palatoglossus and the palatopharyngeus are muscular connections between the soft palate and the tongue and the lower areas of the pharynx. The elastic lymphatic tonsil has a trabecular framework of connective tissue which springs from and is anchored to the tonsillar surface of the capsule. This capsule is loosely attached to the areolar tissue lying between it and the superior constrictor. The capsule and its adjacent tonsil are anchored along the free margin of the palatoglossus and the palatopharyngeus. It can be seen that the tonsil swings as an elastic bumper between the pillar muscles, and by virtue of its looser attachment to the superior constrictor permits an accommodation between these muscles necessary in their varying contractions.

The tonsil also serves to support and hold out the pillars in their advanced positions in the pharynx. The ablation of the tonsil and its capsule obliterates this function, the arches atrophy, dwindle into the lateral walls, widen the faucial space, lose their own direct function, and at the same time lessen their action upon the soft palate, the tongue, and the larynx. It should be recognized in this connection that a person with hypertrophied or diseased tonsils is undoubtedly benefited in many ways by complete capsular enucleation, but this should not blind us as to whether the improvement is only a proportionate one and not the best obtainable. In cases in which the crypts of the tonsil have become diseased the writer advocates the retention of a shallow layer of tonsil and of course the capsule. Some crypts will remain, but these are shallow and usually return to health. Occasionally he removes a wedge-shaped piece from their center. The absence of the greater degree of unyielding cicatricial tissue that forms when the capsule is removed offers advantages, since scar tissue is as pernicious in the fauces as elsewhere in the body. Briefly, the plea is for the skillful removal of the major part of the tonsil in most cases and the removal of tonsil and capsule in a small minority.

5. Special Points in Abdominal Surgery Emphasized by Military Experience.—George W. Crile. (See MEDICAL RECORD, Vol. xcvi, No. 4, p. 176.)

6. Value of Convalescent Blood and Serums in the Treatment of Influenzal Pneumonia.—Henry F. Stoll. (See MEDICAL RECORD, Vol. xcvi, No. 5, p. 217.)

7. Treatment of Influenza by Means Other Than Vaccines and Serums.—James B. Herrick. (See MEDICAL RECORD, Vol. xcvi, No. 5, p. 217.)

9. Infections of Wounds of War, with Special Reference to Gas Gangrene.—Roswell T. Pettit describes the work done in the transportable laboratory assigned to evacuation hospital No. 8 during the St. Mihiel and Argonne-Meuse operations. An effort was made to obtain information of a clinical character, such as that relating to the time between the injury to the patient and the operation; exposure to wet and cold; influence of shock and exsanguination; character of wounds; impairment of local circulation; involvement of bone; character of the soil over which the fighting occurred, and, lastly, the nature and influence of operative interference. Along bacteriological lines a special effort was made to secure the more important anaerobes, such as *B welchii, Vibrion septique, B. edematiens,* and *B. sporogenes* The hemolytic and nonhemolytic varieties of streptococci were studied in cases in which gangrene had developed and in those in which it developed later, and also in cases showing no evidence of gas gangrene at any time. Between September 10, and November 13, 1918, 4,377 patients suffering from wounds received in action were received. During this period there were 363 deaths in the hospital. Gas gangrene was the most important cause of death, 17 per cent. of the deaths being due to this cause. In 90 per cent. of the cases of gas gangrene the infection was well developed at the time of admission to the hospital. The average length of time between injury and operation in 162 cases of gangrene was 41.8 hours. In 349 similar severely wounded nontransportable cases, in which gas gangrene did not develop, the average length of time between injury and operation was 24.67 hours. These figures emphasize the importance of early operation in preventing gas gangrene. Careful bacteriological examinations were made in 890 wounds, subcultures being made in all cases in litmus milk, on Veillon agar, and on blood agar slants. Of these 890 wounds 53 per cent. were found to contain anaerobic bacilli, and 67 per cent. of these at no time showed clinical evidence of gas infection. Of the gas gangrene cases, 3 per cent. developed after operation (débridement), while in 29 per cent. gas gangrene was clinically evident at the time the bacteriological examination was made. It was thus seen that, in the writer's experience, more than two-thirds of the wounds contaminated with anaerobes did not develop gangrene. In 139 cases in which cultures were taken directly from the wounds the relation of the *B welchii* to the other anaerobes in cases of gas gangrene clinically determined was as follows: *B. welchii* was the only anaerobe found in 14 per cent. of the cases; *B. welchii* was absent, but other anaerobes were found in culture in 21 per cent.; *B welchii* and other anaerobes were found together in 65 per cent. A combination of *B. welchii* and other anaerobes was thus found in two-thirds of the cases examined. A statistical study of the relative frequency of the streptococcus, both hemolytic and nonhemolytic, was made in cases free from gangrene and in cases in which gangrene was clinically present. The results show that the streptococcus—both hemolytic and nonhemolytic—was more frequent in gangrenous wounds than in nongangrenous wounds. The writer concludes that: (1) the most important factor in dealing with gangrene is early operation, and that this is a matter of transportation; (2) a majority of wounds are contaminated with anaerobic bacteria without the development of gas gangrene; (3) many cases of gas gangrene are due to anaerobes other than *B welchii;* (4) in most cases of gangrene *B. welchii* is associated with other anaerobic bacteria, and (5) the streptococcus (both hemolytic and nonhemolytic) is apparently of little importance in the production of gas gangrene.

The Lancet.

July 26, 1919.

1. Arris and Gale Lecture on the Initiation of Wound Shock and Its Relation to Surgical Shock. Delivered before the Royal College of Surgeons of England. E. M. Cowell.
2. Jaundice Among the British Troops in Northern Italy. H. H. Tooth and E. G. Pringle.
3. The Effects of Artificial Pneumothorax. S. Vere Pearson.
4. Outbreaks of Cerebrospinal Fever in Relation to Atmospheric Humidity: Influence of the Humidity of Overcrowding. Arthur Compton.
5. Malaria from the Surgeon's Standpoint. Marguerita White.

3. The Effects of Artificial Pneumothorax.—S. Vere Pearson relates his experience gained from twenty-one patients with severe pulmonary tuberculosis in whom he induced artificial pneumothorax, with the exception of one case that developed a spontaneous hydropneumothorax which he converted into a controlled pneumothorax. Eleven of these twenty-one cases are still alive, and all save two are enjoying good health and following their usual vocations. Nearly all of the ten who have died had their symptoms much alleviated and their lives materially prolonged, in several instances by years, during which they enjoyed fairly good health and followed their occupations. In nearly every one of these twenty-one cases a situation had been reached which was quite hopeless apart from artificial pneumothorax. In the case of those with an effective pneumothorax who are still alive, the average time to date from the induction of the artificial pneumothorax amounts to 4¾ years, the longest time being 7¾ years and the shortest 2½ years. In the earlier stages of the treatment, up to about eighteen months, the writer believes there is greater likelihood of making a mistake by injecting gas too seldom and taking the pressures too high rather than erring in the opposite directions. He is convinced that the abandonment of the injections in a successful case after too short a period is a far worse error than the continuance of refills too long. It is by no means an invariable rule for the pleural surfaces to become adherent after injections have been given up. Every endeavor should be made to keep the pneumothorax cavity a closed one. The only excuse for disregard of this rule is the presence of secondary microorganisms. In none of the writer's cases has this happened. Those cases which develop fluid (about 70

per cent.) in the course of treatment need watching with special care. In discussing anatomical and physiological peculiarities which are met after the second year attention is called to the fact that in many cases the ribs come very close together by degrees, and in most the inflated side of the chest becomes partly filled by much displaced mediastinal and subdiaphragmatic organs. Occasionally the mobility of the mediastinum and its contents is largely lost and the heart becomes more or less anchored and displaced to the side with the compressed lung. But more frequently the displacement is altered in amount by a refill, even years after the starting of the pneumothorax. Considerable thickening of the pleura, especially the parietal pleura, occurs in a moderate number of patients by the third year. The practised hand can usually feel and gauge this at the time when the needle is inserted for a refill, and the golden rule must be observed of never giving any gas unless the appropriate oscillations are present. Among the physiological peculiarities belonging more especially to the late stages of treatment the low pressure readings are important, because before starting the refill of gas preparations for the low negative pressures must be made. These are prone to occur especially when the intervals between refills are long—two or more months. Under such circumstances it is necessary to see that there are 7 to 10 cm. or more for some cases of a negative pressure in the gas bottle just before starting, and to take care that the bulb at the top of the negative stem of the manometer is large enough. Another fairly common physiological peculiarity is that the restoration to health of a person accustomed to severe illness may result in a disinclination to continue the refills of gas for a reasonable time. Such carelessness simply courts relapse, disaster, and death. Fluid in the chest may usually be localized by percussion, *x*-ray examination, to a small extent by the sensations of the patient, and especially by noticing the peculiar metallic, ringing nature of the splash when the fluid is within the chest as compared with the duller resonance to the ear, applied by stethoscope or held close to the patient when shaken, if the fluid is only a stomach splash. It is customary to keep pressures rather higher in cases having fluid than in those who do not have it. It is a good thing not to interfere with fluid unless obliged to do so through the chest becoming very full or for some similar reason. But both these rules can be followed too closely in the late stages of treatment. During the fourth year after the initial induction, in cases of fluid in which an effective pneumothorax has been produced, it is as well sometimes not to be too readily deterred from continuing the treatment by such difficulties as fluid getting into the gas needle or pus flakes into the fluid needle. The remedy of each of these troubles is obviously withdrawal of fluid and reduction of pleural pressures thereby before attempting to give a refill of gas in the one case, and the use of a larger bored needle or trocar in the other. It is advisable if one has to resort to artificial pneumothorax to keep it up for at least three years. Under the following conditions an occasional injection should be given for four years: (1) if the patient is over thirty-three years of age and has lost the resiliency and recuperative powers of youth; (2) if the compressed lung was a fairly useless one before the initial injection, and if, in addition, it was producing chronic poisoning; (3) if things are going well during the maintenance of the compression. Compression may have to be maintained indefinitely either because the patient's state is more comfortable and he feels more sure of himself with periodic refills, or because the compressed lung does not re-expand. No hard and fast rules can be laid down regarding the spacing of doses in the late stages of treatment, nor respecting the pressures.

2. Eclampsia: Its Prevention and Treatment.—A. Lapthorn Smith considers eclampsia a preventable disease, and one which in a few years, like many others equally fatal, might be made entirely to disappear. He believes that many of the lives lost by the "wait and see" method of treatment might be saved by a policy of prompt action. The presence or absence of albumin in the urine is such a sure diagnostic test that if routine examinations were carried out by doctors at the end of the sixth, seventh, eighth, and ninth months, and if all midwives and nurses would instruct all women whom they were engaged to attend regarding the importance of going to a doctor for examination of the urine two, three, or four months before delivery was due, practically every case would be detected in time to be treated so that convulsions would be prevented. When albumin is detected in an early case the examination of the urine every week is a wise precaution. Another point that has been well established is that the amount of albumin in the urine can be greatly reduced, as well as the quantity of toxins, by a certain diet, while they are both increased by other articles of food. Another point that has come to be recognized is that the toxin is either urea or one of the products of nitrogen. Hence, abstention from fish, flesh, or fowl is at once followed by a marked decrease in albuminuria. As soon as albumin is detected in a pregnant woman's urine in a slight amount, she should be instructed to dress warmly and to avoid cold and wet, to drink larger quantities of water, and, if she can afford it, to give the preference to mineral and alkaline waters, such as Vichy, of which she should use not less than a bottle a day. If anemic she is given mild preparations of iron to make up for the cutting down of her allowance of meat, although she may continue with fish as long as the albumin is lessening or absent. In addition alkalis should be administered, a very useful one being mist. rhei et sodæ suitably flavored and disguised. Exercise should be encouraged, either as work in the house or walking out of doors. When a woman comes for the first time at the end of the sixth month with a considerable amount of albumin, she should be put to bed on an absolute milk diet, and hygienic and other dietetic measures may then keep the amount of albumin within safe limits. When hesitating about interrupting the pregnancy we must keep in mind the danger of injury to the brain. A number of cases of paralysis are on record, and the writer has seen two due to brain lesions during the first convulsion. Chloral, chloroform, veratrum viride, and venesection should be discarded, because they lower arterial tension and bring about a condition akin to shock, so that the woman is in a bad condition to undergo any surgical procedure. On the other hand, a hypodermic of morphine, one-half grain with one-hundredth of atropine, is effective and does not stop the secretion of urine as has been supposed by some. One should also promptly supply water either by mouth or per rectum. If, after having done these things, a convulsion comes on, all are agreed that there must be no delay in emptying the uterus with the smallest amount of trauma and shock possible. All procedures included under the term *accouchement forcé* must be discarded, as well as vaginal cesarean section, and craniotomy. Abdominal cesarean section, performed by an experienced operator, is one of the safest operations in surgery for the mother, and enormously increases the chances of the child if performed after the end of the seventh month. One well known operator has operated on 550 cases of eclampsia within one hour after the first convulsion without a single death. The best time to operate is before labor begins. A case of eclampsia must not be regarded as a one-man case. There must be three doctors and a good trained nurse if every case is to be saved.

5. Narcotic Drug Addiction in the New Born: Report of a Case. Christian F. J. Laasé.

2. Radiotherapy: Indications and Results Obtained When Properly Used.—D. T. Keith and J. P. Keith believe that in superficial epithelioma a larger proportion can be cured by proper application of the *x*-ray, which includes proper filtering of the rays, than with the knife, caustics and cautery combined. This is especially true of epithelioma involving the face, and the scarring is much less than from other methods of removal. The pain from surgery, caustics or cautery, ranges from the mildest to the most severe, whereas under radiotherapy the patient remains practically free from pain. Reaction in the tumor and surrounding glandular area may be so marked as to cause pain for twenty-four to forty-eight hours, but it is usually not severe. In malignant tumors about the face which by secondary involvement have reached adjacent glandular areas, the authors are positive more benefit can be obtained by radiation, fulguration, and surgery than by the mutilating operative procedures hitherto practised. Several surgeons are now referring to them their patients after radical breast operations for radiotherapy as soon as they are able to leave the hospital. A few years hence complete statistics will be available showing the results obtained by this method of treatment. At present they have under observation and treatment by radiotherapy several patients with uterine disorders ranging in age from thirty-one to forty-six years, and thus far the results obtained have been satisfactory. In three of these it is expected that an artificial menopause will be produced, and neither patient has menstruated more than once since treatment was commenced six months ago. In two others continuous bleeding for more than one year has been controlled within two weeks after treatment was begun, the patients experiencing normal menstruation two weeks later, excepting that the flow was very profuse. The authors' greatest objection to the employment of radiotherapy in uterine affections is the likelihood of mistaken diagnoses, as in such instances their efforts might prove futile.

The results in goiter have been satisfactory, although only a few cases of this kind have been treated. All the patients treated for splenomyelogenous leucemia have improved rapidly and have remained comfortable under frequent applications of the *x*-ray, some of them showing no indications for further treatment for six or eight months. A blood examination is required at least every four to six weeks to keep a proper index in these cases. Blood changes are noted from three to six months earlier than clinical symptoms. In eczema every patient treated by radiotherapy has shown immediate improvement. In a few cases the results obtained have been brilliant and seem to be permanent. There are many other skin lesions in which definite results have been reported, but the authors' observations have been too limited to warrant conclusions from personal experience. At present they have under treatment six or seven patients with psoriasis, and hope to give a detailed report with their conclusions concerning these cases at a later date.

3. Prophylaxis of Venereal Diseases in Cuba.—Lopez Silvero gives some facts about the increase of venereal diseases in Cuba. At the Mercedes Hospital the venereal cases are 15 per cent. of the total cases, the increase having been gradual but steady since 1900. The same has been observed at the Tamayo Dispensary, where about 10 per cent. of the cases are due to syphilis and gonorrhea. In the Cuban Navy there were, from 1914 to 1917, 1,792 cases of venereal diseases, of which 965 were gonorrheal cases and the remaining syphilis. In the Army, in one year, from 1915 to 1916, there were treated 769 cases of syphilis and 710 cases of gonorrhea. Lopez urges the institution of prophylactic measures.

5. Subconjunctival Hemorrhages.—Fernandez cites a curious case in which the patient had bilateral and extensive subconjunctival hemorrhages, the only etiological factor being the prolonged crying the patient had done by reason of the intense grief caused by the death of the father.

Affect Disturbances in Children.—Frank relates some striking instances of sexual motivation of incomprehensible behavior in children of which one may suffice. Walter —— had been a remarkably good and bright boy and prize winner in the school. All at once, without warning, he turned to a most abandoned and perverse character. He lied without limit and stole and obtained money by most precocious artifices so that his father had to warn the tradesmen that he was quite irresponsible. The boy was flogged and told exactly what he was repeatedly, but to no purpose. He was subjected to all kinds of penalties, and even the aid of the police was enlisted. The author was some time in gaining the boy's confidence. He catered to his weaknesses, such as love of chocolate, and finally learned the secret which the boy let out involuntarily and then bitterly regretted. Either the mother had ignored its full bearing or had chosen to be silent about it. While the boy was still well behaved a beautiful servant girl had been hired and had struck up an innocent friendship with the boy. At first he simply preferred the girl to his mother as a companion, but the affection at last ended in the boy's seduction by the girl. The mother then promptly discharged the servant as soon as she learned of her misconduct, although perhaps not fully aware of the degree of intimacy.

The boy blamed the author for extorting his secret, cursed and raged at him and would not see him again. To retrace our steps, the moment the girl was discharged the boy "went bad" and showed hatred, first to the mother and only later and to a less degree to the father, who had played no active rôle in the dismissal. The patient was finally sent to a small private institution, where he showed a marked irritability and hatred toward his mates. After great patience and tolerance, which required about two months, the boy became tractable and was sent home, where he behaved as if nothing had happened. He had acquired such insight into his case that he took the author back into favor and they have been friends ever since.

Book Reviews.

THE SCIENCE AND ART OF DEEP BREATHING as a Prophylactic and Therapeutic Agent in Consumption. By SHOZABURO OTABE, M.B., Tokio; M.B., Bâle; Assistant Medical Officer, Kensington Infirmary, London; Formerly Assistant Medical Superintendent, National Sanatorium, Kent; Assistant Medical Officer, Baguley Sanatorium, Cheshire; Assistant, the Bacteriological Institution of Tokio Charity Hospital Medical College, Tokio. New York: William Wood & Company, 1919.

IT is a curious and deplorable fact that the majority of mankind does not breathe as it should and in consequence fails to enjoy the degree of mental and physical vigor that is its due. All books, therefore, which call attention to the desirability of deep breathing and give directions for its performance are to be welcomed. The author of this book is to be commended for his missionary efforts in this direction and for the sound arguments he advances to convince his readers of the advantages to be derived from systematic breathing exercises. We think, however, he is inclined to take a little too much credit to himself for the advocacy of this truth which he says he discovered at the early age of thirteen years. Not to mention the Buddhists in India, Japan, and elsewhere who have raised the respiratory process to an art, the western scientists have for long insisted upon the value of deep breathing in the prevention of respiratory diseases and in promoting physical well being in general. That Dr. Otabe has ignored this fact does not prove that he is ignorant of it; indeed, the fact that several of his figures illustrating breathing exercises are photographic reproductions of illustrations of an article by Dr. Knopf of this city in the "Twentieth Century Practice of Medicine" (to which, however, he gives no credit) bears witness to his knowledge that the method was known and practised in the western world even before his discovery at the age of thirteen. This, however, does not detract from the value of Dr. Otabe's work or weaken his arguments in support of the useful practice of deep breathing.

CHEERIO! By HAROLD M. HAYS, Major, M. C., U. S. A. New York: Alfred A. Knopf, 1919.

MAJOR HAYS was one of the Medical Reserve Corps officers who volunteered his services early in the war and was loaned to the British. This book is his story of his experiences in the advanced medical units in the British Expeditionary Force and presents a vivid picture of the feelings of the civilian doctor suddenly projected into military surroundings and associating with veterans, many of whom had been at war for four long years. His warm appreciation of the British officer and his tribute to the "Tommy" will not be thought exaggerated by any who have had experience with them. His picture of his batman is amusing and true to life. The story makes very interesting reading and will be cherished as one of the bright lights in the literature growing out of the war. An appendix contains extracts from several articles which appeared in the Continental Edition of the London *Daily Mail*, all offering evidence of the brutality of the unspeakable German fiend toward British prisoners.

THE DON QUIXOTE OF PSYCHIATRY. By VICTOR ROBINSON. New York: Historico-Medical Press, 1919.

"A CHAPTER in the history of American Medicine, containing information not elsewhere available," as the notice of this book expresses it, it includes more especially the biography of Shobal Vail Clevenger. But the story of Clevenger's life, while it forms the backbone of the book, serves also as a frame upon which are hung brief sketches of a number of men who have been prominent in American Medicine. The text is supplemented with numerous photographs of the men mentioned. It is written in an easy, familiar style, and makes very interesting reading. It has always seemed to us to be a pity that the modern American physician apparently took so little interest in the history of his profession, and it is always gratifying when historical publications appear. Many men will perhaps be surprised to find how rapidly time will pass when they read this book. The author, unfortunately we think, is a devotee of the so-called "simplified spelling," a reform which he classes with the sterilization of defectives and the abolition of fraternities and intercollegiate athletic contests. But he not only uses it himself, but forces all of his authorities into it, so that his many quotations from letters, Civil War dispatches, and the like are all tortured into this orthography. This is surely a questionable practice, for a quotation to be correct should copy accurately words, spelling, and punctuation. This protest is none the less earnest because it will probably be ignored.

LE FRANÇAIS ENSEIGNÉ PAR LA MÉTHODE INTUITIVE ET DIRECTE. Por P. DESSAGNES, Agrégé de l'Université; Professeur au Lycée Louis-le-Grand, et à l'Ecole supérieure de Commerce de Paris. Paris: Masson et Cie., 1919.

THIS is the elementary volume of a new course for the teaching of French to English-speaking people. It is based on the principle of the direct method, the pupil using only French from the beginning. Various objects are represented by pictures and these enter as elements in the composition of simple sentences, the meaning of which is evident. Gradually the pupil is carried along from elementary sentences to more complex constructions, learning thus the essentials of the grammar, and insensibly and with no drudgery acquiring an idiomatic use of the language. The book would have been very useful to our doughboys had it appeared earlier, and it can safely be recommended to all beginners in French.

SURGERY IN WAR. By ALFRED J. HULL, F. R. C. S., Lieut.-Col. Royal Army Medical Corps; Surgeon, British Expeditionary Force, France; Late Lecturer on Surgical Pathology, Royal Army Medical College, Milbank; and Surgeon, Queen Alexandra Military Hospital. With a Preface by Lieut.-Gen. T. H. J. C. GOODWIN, C.B., C.M.G., D.S.O., Director-General, Army Medical Service. Second Edition. Philadelphia: P. Blakiston's Son & Co., 1919.

WHILE this edition of Hull's work did not appear until after the armistice was signed, it contains so much that is applicable to peace time surgery that it still remains a very useful and valuable work. It is by far the best book on the subject that we have seen; and we are quite willing to accept as true the statement made by the reviewer in one of the leading British journals that this book may justly be regarded as the standard textbook on the surgery of this war, and again when he says that it is the leading textbook upon the subject in our language.

The first edition was published early in the war when the books on war surgery available were few in number and almost totally inadequate in view of the changed conditions prevailing in this war. On account of its accuracy and relative completeness, Hull's book was almost immediately accepted as the standard. In time, as ingenuity and experience taught many other and often better methods of treatment, revision was demanded. In this revision Hull called to his aid a number of men especially skilled in certain particular lines; so that the scope was broadened, the book enlarged, and made more authoritative. The added contributors and their subjects are: E. M. Pilcher, who has written a very interesting introduction; W. Miller, who covers Gunshot Wounds of the Chest; C. H. Browning, Tetanus; A. A. W. Petrie, Wound Infection and Anaerobic Infection; Owen W. Richards, Wounds of the Abdomen; R. H. Jocelyn Swan, Gunshot Injuries of the Peripheral Nerves and the Later Treatment of Bone Injuries; and H. E. H. Tracy, Gunshot Wounds of the Jaw and Face. All of these collaborators have covered their subjects well; and that is particularly true of the sections on wounds of the chest and abdomen. Hull's own portions form the backbone of the book, and could have been written so well only by a man who has both a talent for clear, concise writing and a comprehensive grasp of his subject. While the author says in his preface that the book is not intended to be in any sense complete, and that symptomatology and details of treatment which are found in textbooks of general surgery have not been repeated, the lack of completeness apparently means simply the leaving out of minor matters, symptomatology is given when necessary in arriving at a diagnosis, and the treatment given includes the best and latest that surgeons of the Allied armies have devised.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventieth Annual Session Held at Atlantic City, N. J., June 9, 10, 11, 12, and 13, 1919.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 218.*)

SECTION ON OBSTETRICS, GYNECOLOGY, AND ABDOMINAL SURGERY.

Third Day—Friday, June 13.

Election of Officers.—The following officers were elected: *Chairman*, Dr. Reuben Peterson, Ann Arbor; *Vice-Chairman*, Dr. Francis Reder, St. Louis; *Secretary*, Dr. Sidney A. Chalfant, Pittsburgh; *Delegate*, Dr. Lewis S. McMurtry, Louisville; *Alternate*, Dr. Rufus B. Hall, Cincinnati.

Trendelenburg Ether Anesthesia in Pelvic Surgery.—Dr. DONALD GUTHRIE of Sayre, Pa., read this paper. He said that during an operation it was often possible for the surgeon to predict what sort of convalescence his patient was going to have. A stormy convalescence was sure to follow any degree of trauma to the small intestine, while the large gut could be handled with relative impunity. He had perfected a method whose salient feature was placing the patient on the table before the anesthetic was started in the Trendelenburg position, the object being to rid the pelvis of small intestine. A *sine qua non* was a skilled and tactful anesthetist. He had often been asked the objections to beginning the operation in the dorsal position and changing later, but he found by experience that if this change were made before anesthesia was complete the patient became alarmed and if the change were delayed until it was complete the result was very unsatisfactory. The patient was placed on the operating table in a high Trendelenburg position before anesthesia was started. The arms were fastened with a gauze bandage, the legs were flexed, and the operation started; absolute quiet should prevail in the room during the administration. A small hole was made in the peritoneum and the abdominal walls lifted vertically up; this would cause an inrush of air, freeing the pelvis of the coil or two of small intestine remaining. By the use of this method, only one small piece of gauze was usually necessary, instead of a number of them, as with other methods. He then showed lantern slides, illustrating this method.

Dr. JOHN O. POLAK of Brooklyn endorsed this method and said that it had found favor abroad, but was not being taken up here as generally as it should be. The use of pads in the abdominal cavity was productive of trauma, no matter what their material; this had been demonstrated by animal experimentation. If no pads were used, convalescence would be easy. A vicious practice was the transfer of the anesthetized patient from another table to the operating one—it was a waste of time and ether and often woke up the patient. The operating table should be mobile and be used for anesthetizing. Instead of using a surcingle and flexing the legs he extended them. He did not believe the method was feasible for gas and ether.

Dr. ALBERT J. OCHSNER of Chicago did not believe the time of elevating the foot of the bed was of so much moment provided only it was at least several minutes before the operation. About twenty years ago the observation was made that in the Trendelenburg position the patient did not inspire mucus and there was less ether pneumonia. This was true and another advantage of this method. He had always ordered the foot of the bed elevated before the patient was taken into the operating room.

Dr. DONALD C. BALFOUR of Rochester, Minnesota, endorsed the method, but preferred its application later when the patient was no longer conscious. He attributed a great deal of operative trauma to the impatience of surgeons who were not willing to wait a few minutes, but tried to force the intestines out of the pelvis, causing the patient to resist and use the diaphragm.

Dr. GUTHRIE said in closing that he wished to emphasize two points: the importance of lifting the abdominal wall well up, and the importance of the really skilled anesthetist.

Abdominal Surgery Under Local Anesthesia.—Dr. ROBERT E. FARR of Minneapolis read this paper. He said that one of the greatest drawbacks with which local anesthesia had had to contend was its discussion by men not skilled in it who compared it unfavorably with general. Men who had become expert in local anesthesia, however, were enthusiastic about it. Most big surgeons, he said, stood solidly for general anesthesia, but the more experience one had with the local the more one liked it. He would not mention all the advantages of local, for they had been gone over so often, but he believed one of the chief ones was that it gave a negative intraabdominal pressure, the organs were in a natural position and not gorged. To be sure the viscera could not be delivered and masses dealt with so readily and there could not be so much digital examination, but if we confined the method to indicated cases and developed visual examination it was very valuable. He described the technique, which was by direct infiltration, except for hernia. The circular method as well as that of nerve blocking took too much time, he thought, and required great expertness for success. He used the pneumatic injector devised by himself in place of syringes; this gave a steady flow and was easy to handle. He stressed two important points: 1. No distress was caused the patient at any time; the initial wheal was intradermal and painful, but not more so than any hypodermic. It was simpler to tell the patient he was to get a hypodermic. Through this first wheal a four-inch needle was introduced and carried beneath the skin. Any number of others might then be made. (He showed a number of diagrams illustrating the technique.) The second important point was the *vertical retraction* of the abdominal wall; with this no gauze was required; in fact, he never used it, except to prevent soiling. Appendices had been seen by hundreds in their normal habitats, and the intestines were touched only at the point where the needle went through the large bowel. In many instances children under fifteen had been given local anesthesia by this method, and in only seven cases had it been necessary to revert to ether. Infants must be restrained; however, it had been used successfully even in cases of hypertrophic pyloric stenosis, without causing the baby to cry. His conclusions were that local anesthesia should no longer be confined to minor operations or to patients who could not take a general anesthetic. It was more comfortable and less dangerous than general anesthesia, applicable even to children, and entirely suitable for abdominal surgery.

Dr. PENN-GASKELL SKILLERN, JR., of Philadelphia said that this method was a great advance in surgical anesthesia; it was operating *de luxe* He had used Farr's apparatus for several years and found it infinnitely superior to the constant taking up and putting down syringes. This method also developed a gentleness of touch which benefited the patient. Local anesthesia had not made the progress that it should. In acute intestinal obstruction it was the best method.

Dr. CHARLES N. COWDEN of Nashville, Tennessee, said that there had been a reaction lately in favor of local anesthesia, and the surgeon who was cultivating it was missing a great opportunity. The laity were becoming educated and demanding it, on account of the unpleasant after effects of ether. The toxicity of cocaine was a drawback, but novocaine was practically innocuous. Surgeons accustomed to ether did not always make good local anesthetists, for they had not cultivated the requisite gentleness of touch. Even slight roughness would mar the operation. The impression held in the past that quinine and urea had to be used was a drawback, but we had gotten away from that idea. The automatic injector was a great help.

Dr. J. A. RUBEN of Pittsburgh said that local anesthesia was the coming thing. He had used it for six years; the first patient had to be persuaded at great length, but nowadays many asked for it. He believed that infiltration was all right for the initial incision. We had an asentic necrosis in some cases which hurt the method and kept the patient in bed a week or two longer. The great advantage of the method was the clean, dry operative wound.

Dr. A. C. Scott of Temple, Texas, said he approved the paper in part, but took exception to one or two points. In exploring the abdomen under local anesthesia there was a limit: the peritoneum could be anesthetized only partially and the whole abdominal cavity could not be. Also we could not form a clear idea of existing conditions in the upper part of the abdomen when the incision was in the lower part; the sense of touch was necessary. In working on the peritoneum near the incision he slipped the finger under the peritoneum for several inches, then stuck the needle through the wound, touching the finger; this would anesthetize the subperitoneal tissue. Traction on the mesentery gave pain, and this could hardly be avoided. The mesoappendix was especially difficult. He thought the trouble was that we tried to apply a good thing to too many cases.

Dr. Farr, in closing, said that he did not believe necrosis of the skin would ever occur if we used less than 5 per cent. adrenalin. Also we should use the intradermal method, rather than the subdermal. It was a good thing for practically all cases, and surgeons should spend more time learning it.

The Efficiency of Surgical Treatment in the Bleeding Type of Gastric and Duodenal Ulcer.—Dr. Donald C. Balfour of Rochester, Minnesota, read this paper. He said that hematemesis was the source of much diagnostic difficulty. He wished to discuss two groups of cases: 1. Where there was bleeding, but no gross lesion. 2. Where an operation had failed to relieve the condition. He quoted a case showing both phases. This patient was operated on for supposed gastric ulcer, but the symptoms had not been relieved. The condition proved to be a "strawberry" gall-bladder and was cured by operation. The first requisite in all patients with a history of hematemesis was to determine the cause of the bleeding: for this a good history and actinograms taken by an expert were essential. From one-fifth to one-fourth of all gastric and duodenal ulcers exhibited bleeding. Formerly various operations were done, but the ulcer itself was not attacked. He quoted the following table of statistics compiled at the Mayo clinic:

Period Covered: 1906-1918.

	Duodenal Ulcer.	Gastric Ulcer.
Cases operated on, giving history of bleeding	2875	863
Operative mortality	1.6%	3%
Bleeding before operation	583, or 20%	222, or 26%
Post-operative history obtained	491	180
Bleeding after operation	63, or 12.7%	15, or 8%
No bleeding before operation, but bleeding afterwards	20, or 0.9%	2, or 0.3%

The radical treatment of gastric ulcer was advocated on account of the possibility of malignancy. A non-operative treatment meant a larger mortality later. In duodenal ulcers there was not that tendency to malignancy. It was noted that in all the patients with duodenal ulcer who bled after operation there had *not* been both excision and gastroenterostomy, and this was true also of the gastric ulcer cases. In other words, gastroenterostomy alone was not sufficient in these cases. Radical treatment of the ulcer never caused recurrence or malignancy. All methods had been tried, but they had found the actual cautery the safest, most certain and most efficient. (Here slides were shown illustrating the technique of the author's method of excision by the actual cautery). He said that there was an actual perforation in all these cases, so obvious in many of them that a probe could be introduced, and this served as a guide for the cautery.

Dr. Raymond P. Sullivan of Brooklyn was impressed with the small incidence of bleeding in these cases, as this was generally supposed to be a common symptom. In any operation for these ulcers the treatment should be simple and direct. Three methods were available: suture excision, knife excision, and the cautery method. The first named was not much done nowadays on account of its uncertainty. Knife excision, followed by suturing, was perhaps the most popular; its drawbacks were the danger of taking out too much tissue, a possible deforming of the stomach, and the risk of giving access to cancer cells. The cautery method was the best. The ulcer should be disposed of and then a gastroenterostomy done. The latter was never indicated merely for bleeding, however. The varicose condition seen at the cardiac end of the stomach in certain heart affections might cause this symptom. Dr. Balfour's paper dealt with the anterior operation; on the posterior surface we were not able to formulate a routine attack; we must leave it to the surgeon at the time.

Dr. Alfred A. Strauss of Chicago said that gastroenterostomy alone was entirely wrong, we must get rid of the lesion itself just as we did in other parts of the body. We should not be afraid of excising too much, for there was plenty of mucosa. He had found a transfusion of 800 to 1,000 c.c. of physiological salt solution before the operation a splendid idea, for it permitted the most radical operation. It was not always possible to decide whether the ulcer was cancerous or not, so if the time and the facilities were available it was well to cut out a small piece and have it examined immediately.

A New Operation for Duodenal and Gastric Ulcers.—Dr. J. Shelton Horsley of Richmond, Va., read this paper. He pointed out at some length the faults of the old operations. The true test was the result: was it recovery with restored function? Gastroenterostomy was the approved method for gastric and duodenal ulcers. He quoted a paper of Balfour's written about two years ago and also figures given by Smith of Chicago which illuminated the efficiency of this operation. The percentage of complaint-free results was less than fifty; this was not satisfactory. The claim that gastroenterostomy abolished irritation of the ulcer had not been proved, nor that it reduced acidity. Neither of these claims was justified, but it did cause the stomach to empty more rapidly, which was an advantage. Finney's operation was the one usually done and was the best, but not ideal. It was really a method of drainage, and we must remember that the stomach was a hollow, muscular organ, with no lowest point. There were many objections to pyloroplasty. He drew an analogy between these ulcers and those occurring in the lower part of the rectum. These latter did not heal until we performed proctectasia. We would not think of making an artificial anus to treat them, but paralyzed the sphincter temporarily and cauterized the ulcer. This treatment could logically be applied to gastric ulcers. (He showed lantern slides illustrating his technique.) He made an incision about three inches long, beginning one inch within the duodenum and slightly curved on the stomach so as to keep midway between the greater and lesser curvatures. Two inches of the incision were in the stomach and one inch in the duodenum. The ulcer was excised from the mucous surface in duodenal ulcer or by separate incision in gastric ulcer. The incision was sewed up transversely, which placed the angles in healthy tissue within the stomach walls and put out of commission temporarily the pyloric sphincter and the pyloric fibers of the stomach, but preserving the physiological function of the organ. He quoted thirteen cases where this method had been used; eleven of them showed gratifying results. There had been two deaths, but one of these was not attributable in any way to the operation and the other one only partially, if at all.

Dr. J. B. Blake of Boston said that there were three points of especial interest in the paper: (1) The parallel between ulcer at the pylorus and *in ano* had never been pointed out before, but it was a closer one than might be imagined. (2) The function of the pyloric sphincter was discussed by Cannon several years ago. The stomach must not be regarded simply as a hollow bag. The pylorus was a fine piece of mechanism, and if even a part of it was left it would try to fulfill its function. Non-effective operations for ulcer were probably due to various faults. If we could substitute a plastic operation on the pylorus with restoration of function we should do so. (3) The technique described by Dr. Horsley seemed admirable and should be adhered to by other good operators all over the country. Too often surgeons modified each other's operations for no adequate reason.

Dr. A. A. Strauss of Chicago believed that the essay-

ist's operation was perfect, but only if the ulcer were on the anterior surface.

Dr. JOHN T. BOTTOMLEY of Boston said that the important thing was to excise the ulcer and then it did not matter much what else one did, always remembering that an ulcer was the end pathology of something else—the original focus must be found. Years ago Cotton of Boston called attention to the analogy mentioned by Horsley. He did not believe that the cautery was a sure method.

Dr. GEORGE GOODHUE of Ohio reported the case of a patient whom he knew intimately and who had had an ulcer ligated in the Mayo Clinic: he thought the mortality was much less with this method. There was danger in making the opening too near the cardiac end.

Dr. JOHN J. GILBRIDE of Philadelphia quoted the case of a patient who had died before operation, and at autopsy the ulcer was found in an abnormal location.

Dr. ALBERT J. OCHSNER of Chicago stated that faulty premises were always used in these discussions. In the experiments of Cannon and Blake the stomach was always normal in shape, but the actual organs encountered on the operating table were far different, they were distorted, atonic, and pendulous; when gastroenterostomy was done a helpless bag was aided to become a normal, functionating stomach again.

Dr. MILES F. PORTER of Fort Wayne, Indiana, thought these ulcers really originated elsewhere in the body. Furthermore, even when the patient had a gastric or duodenal ulcer, it could not be assumed that a hemorrhage necessarily had its origin in the ulcer. He reported a case illustrating this.

Dr. WILLIAM J. MAYO of Rochester, Minnesota, was of the opinion that the last word had not yet been said in the matter of ulcer of the stomach. He suggested that Dr. Horsley improve his technique and report again next year. The ulcers which came to surgeons were long-standing—derelicts—which had been treated by practitioners for years. One patient he knew had been cured nine times by as many different doctors. Many of these patients were suffering from a diagnosis of gastric ulcer—and curing a man of a diagnosis by surgery was an ill-advised procedure. Many such instances had been observed in the Mayo Clinic, especially some years ago. The use of silk left a secondary ulcer, and from 2 to 3 per cent. of gastrojejunal ulcers were the result of silk. Its use was abandoned in the Clinic two years ago in favor of catgut. The question was often asked: Does cancer follow ulcer? Personally he thought it did. He had seen reports such as one of from two to three hundred women treated by gastroenterostomy for ulcer and a total absence of cancer incidence. He was inclined to think that these figures suggested a large amount of diagnostic error, for most ulcers occurred in men, anyway. As for the proof sometimes offered of a series of autopsies on patients dying of cancer of the stomach with no antecedent ulcers found he believed that this should be accorded the same value as a statement of autopsies on cancer of the cervix with no inaugural laceration of that part. In these autopsies the disease process had progressed so far that it was impossible to tell what the precursory condition had been. Dr. Wilson, for example, had exhibited fourteen cases where it was impossible to tell which pathological condition was present, ulcer or cancer; later five or six of these patients died of cancer. The insurance companies had investigated the subject of duodenal ulcers and found the mortality better than normal for the first five years, but in the case of gastric ulcers it was four or five times greater than normal. The difference between the cautery and the knife was that the latter often grafted cancerous tissue. He was afraid to remove part of a lesion with a knife unless he was prepared to operate on the spot. There were three periods in the life of a cell: growth, function, and senility. In the cancer cell there was no functioning, but it divided into embryonic cells. They were about five times as vulnerable as an ordinary cell, and if we used a cautery we killed them easily, much more easily than with a knife.

Dr. C. A. L. REED of Cincinnati said that there was always ptosis in these cases and visceral cyanosis. We must consider such things as angular formations in the mesentery, damming back of the venous circulation, etc. These had the effect first of all of causing gastric catarrh. A large factor in these hemorrhages, both pre- and post-operative, was the venous congestion, and we did not eliminate that at operation.

Dr. BALFOUR said in closing that the surgeon who used the knife for excision might find malignancy at operation, and then he would be in a dilemma—he would wish he had used the cautery. The analogy between the anal and the pyloric ulcers was all right, but after all the ideal treatment of the anal ulcers would be rest. The principal thing was for the stomach surgeon to have an open mind.

Dr. HORSLEY said in closing that he wished to emphasize that his apparently high mortality was not due to the operation *per se*, and these preliminary figures should not be compared to those of a standardized operation. In ulcer *in ano* one put the sphincter at physiological rest, and that is what one should do with the pylorus.

The Treatment of Gunshot Wounds of the Abdomen.—Dr. JOHN H. GIBBON of Philadelphia read this paper. He said that there had been a great improvement of late years in the treatment of gunshot wounds of the head and thorax, but not of those of the abdomen. In the Boer War many cases of perforating wounds of the abdomen recovered without operation, but this was not so in this war. The first essential was to determine whether or not perforation had occurred and what viscera had been hit. Sometimes noninterference was better, in wounds of the liver, for example. If there were multiple wounds in other localities we should be sure that the abdomen had been perforated, not that abdominal wounds were not serious, but because many missiles which *seemed* to enter the abdomen only lodged in the wall, and *vice versa*. Shell wounds were frequent and showed large, irregular openings, with a low pulse and symptoms of shock. These should not be probed. He quoted the case of a young officer with gas poisoning and a slight wound in the left groin, where the abdomen was penetrated in spite of the apparent improbability of this. Good judgment, based on a thorough examination, was indicated. More lives had been lost by not "wasting time" than by making a careful examination. Many wounds of the chest with the missile lying on the diaphragm suggested abdominal perforation by their symptomatology, but recovered without operation. Sometimes a missile went through the abdominal wall and wounded the liver and diaphragm; in such cases no operation was indicated, especially if the missile were small. He had often regretted operating, but very rarely waiting. If the hollow viscera had escaped we should not operate. Nature would stop bleeding from the liver from gunshot wounds quicker than the surgeon could. The abdomen was usually closed without drainage, but wounds of the colon or kidney usually required it. All layers were closed, but the skin and the sutures were left loose in this. Late infection of the abdominal wound never involved the abdominal cavity, differing from wounds of the diaphragm. The mortality was very great, and much of it occurred on the field. Hemorrhage and shock were the usual causes, also very severe wounds. Prisoners with abdominal wounds had a much lower mortality, due doubtless to lack of haste in operating; hence it might be that we should wait until shock was entirely over before we operated, unless hemorrage was present.

Dr. EDWARD W. MEREDITH of Pittsburgh said that he believed in waiting longer than usual before operating. Most cases he saw had gone about twenty hours, and then it was a question of peritonitis. These patients had had a long ambulance ride, suffered from pain, cold, etc., were put in the shock ward and several hours later were much better. He drained about 50 per cent. of the cases. Many handicaps in treating these cases in military life were not present in civil.

Rational Surgery of Visceroptosis.—Dr. ROLAND HAZEN of Paris, Ill., read this paper. He said that the position of the liver was the vital point and if it became ptosed all the other viscera were obliged to follow suit. He described the changes which took place. Merely raising the viscera was not always of avail: it might make the patient comfortable and it might not. The chief troubles were malfusion and tissue strain and we should estimate the disability by these things rather than by the amount of lowering of the tissues

in question. The importance of the hepatic flexure was equal to or greater than that of the cecum or anything else. Rational surgery utilized the principles and methods of nature. Defective fusion of the colon to the flank in the fetus was a primary and fundamental cause of visceroptosis. Primarily, therefore, we induced an anatomically correct replacement and fusion after the pattern of the normal subject. (He showed pictures illustrating the conditions found and their remedy.) After eight years' experience with these principles he investigated the results in over 100 patients and found that the average degree of incapacity before operation was 45 per cent.; after operation it was 9 per cent.

Dr. ROBERT T. MORRIS of New York said that there were a great many of these patients. They represented defective development and cultural limitations. They showed other stigmata such as high palates, etc. Besides the visceroptosis they might exhibit such things as Lane's kinks. On the nervous and mental side they might exhibit disturbances of the autonomic nervous system, manic-depressive psychoses, cyclothymia, melancholia, etc. It was important to do the correct thing with these patients or the trouble would only be aggravated.

Dr. JOHN J. GILBRIDE of Philadelphia said that operation didn't help these cases. He cited the case of a patient on whom various operations had been done without relieving the condition and it was finally discovered that the ilio-hypogastric nerve had been imprisoned in the scar from a kidney operation. A great deal could be done in many instances by scientific diet.

Dr. J. SHELTON HORSLEY of Richmond, Va., believed in operating on patients of this type, but thought it was important that the operation should be done early. The peritoneum was the best material for suspension.

SECTION ON NERVOUS AND MENTAL DISEASES.

Third Day—Friday, June 13.

A Case of Hysterical Hemiplegia, Following a Shrapnel Wound of Scalp.—Dr. HARRY H. DRYSDALE of Cleveland, Ohio, read this paper. He reported the case of a patient who was discharged from the Navy for physical disease, on which account he was first rejected for the Army, but later accepted and eventually sent abroad. He took part in a thrilling rescue in No Man's Land in August, 1917, but received a shrapnel wound on the left side of his head. He was cared for in a Casualty Clearing Station for twenty-four hours, then taken to a Base Hospital, where he was found to have a left-sided hemiplegia. From this time on he was examined frequently in France and England and heard his case discussed many times; he was finally discharged as medically unfit and granted a pension of $50 a month. In January, 1919, he presented himself for treatment at the U. S. Marine Hospital at Cleveland, walking on crutches. He dragged the left leg, carried the left arm close to the body with the left hand firmly contracted. There was a partial left hemianesthesia, the deep reflexes were markedly exaggerated, an apparently complete left Babinski, but no Oppenheim or Gordon, with also sustained clonus of the left ankle. The left arm and leg were paretic and slightly atrophied. There was a depressed area on the left side of the skull, but the radiograph of the skull was negative. Wassermann reaction was negative. The patient was depressed and nervous. He gave a history of having been struck by a piece of timber on the left side of the head, also a history of malaria several years ago, with a one-sided weakness following it; this was later denied. His disability had been diagnosed as organic paralysis with 100% disability, due to contrecoup. The first tendency was to agree with the organic theory, but later on his disability was decided to be functional. He was an emotionally unstable individual and easily upset. The diagnosis of functional disorder was based on this, together with the negative radiograph, discrepancies in the eye signs as given by him and as actually found, and an absolutely negative spinal fluid. He was told that there was no injury to the brain, but that he was suffering from the effects of shock and would get well. Sedatives were used temporarily, but no other medication. He improved from the first. The Babinski sign soon disappeared and the gait improved. He complained of many nervous symptoms; stated, for example, that crowds worried him, and any sort of an emotional experience upset him. He was very fond of sympathy and on one occasion he was seen marching in a parade, exaggerating his limp a great deal. Injections of alcohol into his fingers loosened the contractures and the electric current made them relax. The final examination showed many improvements, but he was still nervously unstable. The conclusions drawn were that this patient presented a confusing neurological picture, especially on account of the Babinski which was hard to explain, and the paralysis on the same side as the flesh wound of the head. A diagnosis of hysteria was suggested and this was not incompatible with the statement that it never arose on the battlefield, as this patient's symptoms did not appear for twenty-four hours. The prognosis was considered good except for the fact that the patient had heard too much talk about his own condition and, furthermore, he had gotten used to depending on a pension.

Dr. ALFRED GORDON of Philadelphia said that the Babinski phenomenon in hysteria had been reported occasionally. Sometimes the whole foot went up in dorsal flexion. We must be sure that we had the Babinski as the originator described it. Care must also be taken with the knee reflex. In such cases as the above the question of compensation was of interest and it was often a problem to determine the justice of their claim.

Dr. TOM A. WILLIAMS of Washington, D. C., said that two factors entered into the case in question. There was a possibility of a deferred reaction resembling a Babinski and also a simulated Babinski. A patient could learn to simulate an ankle clonus as well, but the deception could with care be detected. Another possible explanation was an original lesion which disappeared rapidly, such as meningitis. Such a thing would recover, but the difference was that an organic phenomenon could not be removed by suggestion or persuasion while a psychic one could.

Dr. ALBERT E. STERNE of Indianapolis said that cases such as this should be reported more frequently. We were getting many returning soldiers now, presenting problems, and we wished to give them everything to which they were entitled; even if they were only functionally disabled they were still in a bad way; we should remember, however, that there was always the danger of encouraging an overwhelming flood of these cases against the Government. When people felt badly, they exaggerated their symptoms. The reflexes were often but dubious guides, and this was true even in cases where there was no question of compensation.

Dr. LEWIS J. POLLOCK of Chicago said that in these compensation cases the important thing was to get the patient well and in hysteria if a pecuniary reward was offered it prolonged the disability. This was the principle held to in the French Army, at any rate.

Dr. HUGH T. PATRICK of Chicago objected to the statement that these symptoms disappeared under suggestion; this must be qualified a great deal. The suggestion must be the right sort; some soldiers went many months with their symptoms in spite of all sorts of suggestion. He endorsed Major Pollock's views in regard to compensation.

Dr. W. S. LINDSAY of Topeka, Kan., objected to such a sweeping statement as the one made by Dr. Williams in regard to the exclusion of organic disease.

Dr. FOSTER KENNEDY of New York said that from 1916 to 1918 the British Government pensioned some 25,000 soldiers for "shell shock," owing to a medical misapprehension of the subject at that time; they knew now that it was caused by fear and poor adaptation and not by petechial hemorrhages. The French adopted an attitude which perhaps went to extremes on the other side. In these days of civilian armies we must consider the individual himself. Furthermore it was necessary to have an extremely competent board to make absolutely sure of avoiding diagnostic errors.

Dr. E. E. MAYER of Pittsburgh said that there was a difference between war hysteria and the hysteria seen after the war and the treatment should differ accordingly. The policy of noncompensation might be all right during the war, but not so after the war. The question now was what to do with these patients, what

sort of reeducation to apply, what was the proper compensation, etc.

Dr. JULIUS GRINKER of Chicago said that he had heard the statement made at the gastroenterological section that morning that the diagnosis of hysteria was a confession of perplexity. Unconscious simulation was a symptom of hysteria, of course, but was not the only symptom; no doubt this feature was what was in mind when the statement was made that there should be no compensation. Hysteria was a disease and should receive compensation.

Dr. DRYSDALE said, in closing, that he felt that his paper had served its purpose in starting a discussion. He thought the patient would be better off as a rule without compensation, but he should not be called a malingerer.

Multiple Neuritis of Toxi-Infectious Origin with Especial Reference to Diabetic Polyneuritis.—Dr. ALFRED GORDON of Philadelphia read this paper. He referred to the many causes of multiple neuritis. There were certain characteristic features of the kind seen in diabetes. Those forms seen in various other infections showed still different symptoms, such as rapidity of development, paralysis of certain nerves, and affection of the sphincters. Three cases were seen associated with pneumonia, and in these there was evidence of hepatic disorder. These cases were progressive and tended to be more serious than ordinary. He alluded to other differences from the more common forms. In the cases seen with diabetes it was noted that an increase in the neuritic symptoms always coincided with a flare-up in the diabetic symptoms. He described briefly the treatment.

The Resemblance of the Sensory Symptoms of Diphtheritic Multiple Neuritis to Those of Anemic Cord Changes.—Dr. GEORGE WILSON of Philadelphia read this paper. He said that Dejérine first pointed out these conditions. There was a widespread involvement of the nervous system in diphtheria, as Oppenheim had stated. Many examinations had been made of the nerves in this disease. Degeneration of the posterior columns had been found; various other parts of the cord might be affected. Babinski's sign had often been found, showing an involvement of the pyramidal tracts; cases of this sort were much more likely to prove fatal. He reported the case of a young student who complained of numbness and other sensory symptoms and showed ataxia and other gait disturbances. Two other patients were quoted who showed somewhat similar symptoms. He thought the disease process must be in the cord rather than in the peripheral nerves, for this was the only place where the fibres conveying pain, discrimination of two points, etc., were grouped together.

Dr. W. W. RICHARDSON of Mercer, Pa., said that he had seen many of these cases in France; there they had been attributed to the insufficient use of antitoxin in the early stages.

Nervous System Sequelæ in Three-Day Fever.—Dr. WILLIAM H. ROBEY, JR., of Boston, read this paper. He said that it was written to call attention to the serious nerve sequelæ of influenza. He gave the symptoms of three-day fever as seen in the Army camps. Neural complications were comparatively rare. He quoted several cases, with their neurological examinations. Prognosis, he said, should be guarded in these cases.

Dr. CHARLES A. ROSEWATER of Newark, N. J., asked if he had seen any cases of sudden death following an apparently mild attack of influenza. He quoted one case where the patient had not seemed to be very ill, but dropped dead, and a few weeks later the same thing happened to his daughter.

Dr. W. H. MAYER of Pittsburgh had seen one case of sudden death. It was probably due to myocarditis, just as after any other infection. The only nervous sequela he had seen, peculiar to influenza, was lethargic encephalitis.

Dr. HUGH T. PATRICK of Chicago said that he had seen the knee and ankle reflexes absent, but ankle clonus present. He was at a loss to explain this.

Dr. MAX H. WEINBERG of Pittsburgh thought that these symptoms bore some relation to lethargic encephalitis. He had seen pleocytosis in many of these cases. He would like to know if they were two isolated cases, or merely two quoted from a group of them. If the former, they were probably encephalitis.

Dr. ALFRED GORDON of Philadelphia said that he had seen no sudden deaths following influenza. He had seen three cases of encephalitis lethargica, with cranial nerve involvement. He thought these sudden deaths suggested encephalitis, probably some affection of the mesencephalon. In speaking of the anatomical basis he referred to Marie's work.

Dr. ROBEY, in closing, said that he had seen no cases of sudden death. The cases he had quoted were not thought in France to be influenza, but were held to be infectious from the streptococcus hemolyticus. These cases were all those of nervous sequelæ he had seen.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago and New York, December 2-19, 1918.

(*Continued from page 310.*)

OBSTETRICS (*Continued*).

6. Discuss the bacteriology, clinical history, diagnosis and treatment of acute pelvic inflammation following abortion or delivery at term.

7. What are the essential points in the technic of two different operations for the correction of backward displacements of the uterus? What are the chief indications for each operation?

8. How could you make a diagnosis for or against cancer of the uterus in a case of bleeding in a woman between 40 and 50 years of age?

9. What are the indications for drainage of the abdominal cavity after operations involving opening the cavity?

10. How would you treat a case of visceroptosis severe enough to cause symptoms?

HYGIENE.

1. What measures would you recommend for the control of venereal diseases?

2. What measures would you adopt for the control of malarial fever in a military camp?

3. Explain the mode of spread in the following diseases: (*a*) Yellow fever. (*b*) Trench fever. (*c*) Bubonic plague. (*d*) Yaws.

4. Name three diseases due to defective dietaries, and state briefly corrective measures for each.

5. Discuss the methods by which the following parasites may re-enter the human host: (*a*) *Filari bancrofti.* (*b*) *Taenia saginata.* (*c*) *Trichina spiralis.* (*d*) *Necator americanus.*

MEDICINE.

Answer ten questions, including at least one question each from Groups 8-9, 10-11 and 12-13.

1. (*a*) Describe two clinical disorders of the heart beat. (*b*) Which forms of cardiac arrhythmia indicate a serious disturbance of the heart's action? (*c*) Which forms are most responsive to treatment?

2. (*a*) Give the clinical symptoms of acute pneumonia as it occurs in connection with influenza. (*b*) Give the indications for aspiration in acute serous pleurisy.

3. (*a*) Discuss the clinical diagnosis of carcinoma involving the pylorus of the stomach. (*b*) Discuss the significance of jaundice in gallbladder disease.

4. Describe the changes in temperature, pulse, blood, and the skin characteristic of typhoid fever.

5. (*a*) Discuss the clinical significance of hematuria. (*b*) Give the criteria indicating improvement in a patient with acute nephritis.

6. (*a*) What are the effects of acidosis in diabetes mellitus? (*b*) Discuss the prognosis of diabetes mellitus.

7. (*a*) Discuss the etiology of Hodgkin's disease. (*b*) Give the characteristic clinical symptoms of this disease.

8. (*a*) Discuss angioneurotic edema. (*b*) What is understood by Raynaud's disease?

9. (*a*) Give the initial or preataxic signs of tabes dorsalis. (*b*) Discuss the visceral symptoms of this disease.

10. (*a*) Discuss the etiology of acute chorea in children. (*b*) Outline a plan of treatment for this condition.

11. (*a*) Give the principal clinical symptoms of congenital syphilis. (*b*) What is understood by the late manifestations of congenital syphilis?

12. (*a*) Discuss briefly the principal theories that have been held as to the etiology of pellagra. (*b*) Which do you consider the most reasonable, and why?

13. (*a*) Name the clinical forms of the plague, and describe one of them. (*b*) Discuss the prophylaxis of this disease.

ANSWERS.

OBSTETRICS (*Continued*).

6. *Acute pelvic inflammation following abortion or delivery at term.* The *bacteria* which may cause it are: Streptococcus pyogenes staphylococcus pyogenes aureus, gonococcus, bacillus coli communis, bacillus diphtheriæ, bacillus typhosus. They are generally introduced by the fingers of the physician or nurse, or by instruments, or general lack of cleanliness. *Symptoms:* Chill; rapid rise in temperature, to about 103° or 104° F., higher in the evening than in the morning; sweats; rapid pulse; depression; dry tongue; anorexia; carphologia; scanty, high-colored, albuminous urine; restlessness; sometimes delirium or coma. The uterus is large and tender; the lochia are diminished or suppressed; the milk secretion is often suppressed; pain in the abdomen; peritonitis may develop. *Treatment:* Prophylaxis is of the greatest importance. Purgatives; vaginal douches; some recommend curettage, others decry it; the introduction of antiseptics into the uterus; supportive and general treatment are indicated; specific sera and vaccines have been recommended by some.

"Parametritis frequently follows infected tears of the cervix, or is secondary to puerperal endometritis. There are pain and tenderness at the seat of inflammation, because of the marked inflammatory edema of the parametric tissues, moderate tympanites, frequently nausea; the lochia are scanty; an exudate is found in one or both broad ligaments by abdominal or bimanual examination; the uterus is more or less fixed, sometimes displaced; fluctuation generally may be made out at the seat of the exudate if pus forms. Abscess results in less than 20 per cent. of cases of parametritis. The pus collection may be in the broad ligament, extraperitoneal, or it may be intraperitoneal and encysted, the result of a circumscribed peritonitis and agglutination of surrounding structures, or of walling off by exudate."

Treatment of parametritis: "Hot vaginal douches, several gallons at a temperature of 110° to 120° F. may be given two or three times daily. Local antiseptic and general tonic measures are indicated as in other septic conditions. If an abscess forms it should be evacuated early and drained by the vagina or by extraperitoneal abdominal incision. Operation by the vagina generally is safest, and it best effects drainage. This route should be chosen except when the pus cavity cannot safely be reached from below. In the latter event the incision should be made just above Poupart's ligament and parallel with it, and the pus collection reached extraperitoneally."—(Polak's *Manual of Obstetrics.*)

7. *For backward displacements of uterus:* (1) *Alexander's operation*, which consists of extraperitoneal shortening of the round ligament in the inguinal canal. The essentional points are aseptic and antiseptic precautions, to expose the aponeurosis of the external oblique, secure bleeding points, open the inguinal canal, isolate the round ligament and clear it of fat and cellular tissue, pull on the ligament till the uterus is far enough forward, and then cover the wound with a sterile pad while the opposite side is being treated similarly: both ligaments are then pulled tense, drawn across the symphysis, and stitched with catgut into the inguinal canal. Each stitch is passed through the skin and subcutaneous fat, then through the floor of the exposed canal, then through the round ligament, then through the opposite wall of the canal, and out through the skin. The ligament is stitched into the whole length of the canal, and the excess of ligament is cut off. The wound is then closed, the patient kept in bed for about three weeks, and in some cases a pessary is inserted for a month or six weeks. This operation is only available in the absence of adhesions, inflammations, prolapse, tumors, or pelvic diseases; that is, in uncomplicated cases of backward displacement.

(2) *Ventrosuspension*, in which the uterus is suspended by sutures against the anterior abdominal wall, just above the symphysis. The abdomen is opened in the median line, and any necessary abdominal work is done. "The uterus is suspended by two silk or, better, Pagenstecher linen thread stitches passed through the peritoneum of one side from within, through the inner one-third of the rectus muscle and down through the peritoneum again; through the fundus uteri, between the tubes, taking a bite one-half inch wide and one-quarter inch deep; through the peritoneum and inner one-third of the rectus muscle of the other side and down through the peritoneum again. When the knots are tied, they will be inside the peritoneal cavity. Catgut is not satisfactory because of stretching and premature absorption. An assistant, with one finger in the wound behind the uterus, keeps the intestines out of the way until the knots are tied." (Hirst.) This operation is indicated in women past the child-bearing age, and where there is prolapse as well as retrodisplacement also when other complications are present and where abdominal procedures are necessary.

8. Hemorrhage is generally the first indication of cancer of the uterus and every such case should be viewed with suspicion. Within the ages given every hemorrhage (other than that of normal menstruation) should be a cause for a thorough examination. At first this hemorrhage may be caused by exertion or coitus; and the loss of blood may be slight, but later it increases in amount and is accompanied by other discharges and an offensive odor (in case of carcinoma). The uterus may be freely moveable, moderately enlarged, and the cervix may or may not be normal. On dilating the cervix, a hard irregular ulcerating mass or a soft mass may be found, which on microscopical examination proves to be cancerous. Other possibilities are retained products of conception, extrauterine pregnancy, uterine polypi or fibroids, and endometritis.

9. "*Drainage* is not usually called for in abdominal operations. If the surgeon is careful in his manipulations, and avoids measures which are liable to lead to subsequent oozing, the peritoneum may be closed with safety. When adhesions likely to bleed have been divided, or raw surfaces left such as occur after enucleating a parovarian cyst from the broad ligament, some means should be provided whereby any considerable effusion of fluid can escape, and this can often be best effected by the use of a rubber drainage tube or a Keith's glass tube which can be removed in twenty-four hours. Into the latter it is perhaps well to introduce a strip of aseptic gauze, which will act as a lamp wick, and along which, by capillary action, the effusion finds its way into the general dressing placed over the wound. On the other hand, when an infected focus has been opened and needs to be drained—*e.g.* an acute appendix abscess—surrounding parts must be protected from spread of infection, and this is best accomplished by the use of a rubber drainage tube, around which sterile gauze is packed in such a way as to induce the formation of protective adhesions."—(Rose and Carless' *Surgery.*)

10. *Treatment of visceroptosis:* "The underlying neurasthenic condition demands the most careful attention—hydrotherapy, regulated feeding, general tonics (especially nux vomica), change of scene and air, etc. Gastric hyperacidity or subacidity, flatulence, and constipation must be treated, as mentioned under these headings. Much relief may be afforded by a properly made, fitted, and applied bandage or abdominal supporter; in fact, the bandage in itself may lead to symptomatic cure. Occasionally resort may be had to operative measures—to elevate a markedly displaced stomach or colon, to resect a redundant sigmoid, etc."—(Kelly's *Practice of Medicine.*)

HYGIENE.

1. *Measures for the control of venereal diseases:* Compulsory reporting of all cases to the health authorities, such reports to be confidential; education, by means of pamphlets and personal instruction; the use of a bichloride solution (1:1000) or potassium perman-

ganate (1:500) to cleanse the genitals; a small amount of calomel ointment (20 to 30 per cent.) to be rubbed over the parts immediately after use. The inspection and segregation of "known prostitutes" is not of much service, because the "clandestine prostitute" is more dangerous.

2. *For control of malarial fever in a military camp:* Exclusion of the anopheles mosquito by such use of nets and screens as is possible, also wearing of veils of netting over the head and gloves or mittens on the hands when exposed to infected mosquitoes; frequent fumigation of rooms and tents with formalin or sulphur; constant brushing out of the rafters and ceilings; the destruction of all mosquitoes and larvæ, and the removal of pools and stagnant water where anopheles might breed; kerosene oil spread on the surface of water is beneficial, one pint of oil being used for each 400 square feet of water; prophylactic doses of quinine are of service.

3. *Yellow fever* is spread by the bite of the infected stegomyia mosquito; this mosquito only takes the fever germ from a patient during the first three days that he has the disease; and the mosquito cannot transmit the disease for another twelve days, but after that is infectious for the rest of its life.

Trench fever is believed to be spread by lice; not by the bite of the louse, but by the feces of the louse (which has fed on trench fever cases) being crushed into the wounded surface of the skin. It takes about a week for the louse to become infective in this way.

Bubonic plague is spread by the bite of fleas which have become infected by feeding on the blood of plague rats.

Yaws is probably spread by flies, which transfer the secretions from infected persons to the broken skin of non-infected persons.

4. *Three diseases due to defective dietaries:* Scurvy, rickets, and pellagra.

Scurvy is due to lack of organic acids such as are found in fresh vegetables and fruit, and to excess of salt meat and fish.

Rickets is due to lack of lime salts and animal food, and to excess of starchy foods; in the case of infants, lack of proper milk.

Pellagra is due to an unbalanced diet consisting mainly of corn, and to deficiency of fresh proteins. The diet must be balanced, and made nutritious; fresh proteins (eggs, peas, beans, fresh meat) must be added to the diet.

5. *Filaria bancrofti* develops (partly) in the stomach of the mosquito, passes to the salivary glands of the mosquito, whence it passes into a new human host when the latter is bitten by the mosquito.

Tænia saginata. Man becomes infected with this tapeworm by eating raw or underdone beef which contains the larva.

Trichina spiralis. Man becomes infected by eating trichinous pork (the pig has become infected by eating infected rats or feces or offal).

Necator americanus may enter the human host by boring through the skin or by being ingested with food or water, or by being transferred to the mouth by dirty fingers.

MEDICINE.

1. TWO CLINICAL DISORDERS OF THE HEART BEAT. (1) "*Palpitation* is unduly forcible and sometimes irregular cardiac action, *perceived by the subject.* It may occur in organic disease, but is much more frequently functional and of neurotic origin. Hence it is oftener met with in women than men, and in them is associated with anemia, uterine affections, worry or emotion, and gastric disorders. Neurasthenia and allied nervous conditions predispose to it. In males it is often due to oversmoking or to alcohol, and sometimes to sexual excess or physical overstrain. The attacks are often paroxysmal, and may come on during rest. On examination, the heart's action is found to be forcible, frequently accelerated, and sometimes irregular, but the organ is otherwise normal. *Treatment* consists in removing the cause, allaying the anxiety, and regulating the diet and habits. Tea, coffee, alcohol, and tobacco should be forbidden; and sedatives, such as bromides, or, in other cases, nervine tonics, such as nux vomica, may be required. (2) *Tachycardia*, as the term is loosely used, implies merely increased rapidity of the heart's action, and this condition may be due to the same causes as palpitation, to exophthalmic goiter, to disease of the medulla oblongata, or to paralysis of the vagus in peripheral neuritis. Allbutt, however, would limit the term to *paroxysmal tachycardia*, an affection of which the attacks have an abrupt beginning and ending, are accompanied by restlessness and exhaustion, and last from a few minutes to a few days or even weeks. During the attack the pulse rate may rise to 150, 200, or even 300 beats per minute. Some of the cases end in death from dilatation and cardiac failure. In these cases irregularity is frequent, and slight lesions causing irritation of the bundle of His have been found. In many the *nodal rhythm* is present, *i.e.*, the ventricles and auricles contract simultaneously, the contraction commencing at the auriculo-ventricular node. The *treatment* is *rest*, and sedatives for sleep. Digitalis is occasionally useful."—(Wheeler and Jack's *Handbook of Medicine.*)

Forms of cardiac arrhythmia which indicate a serious disturbance of the heart's action are: Pulsus alternans, and auricular fibrillation; the forms most responsive to treatment are sinus arrhythmia, and extrasystoles.

2. *Acute lobar pneumonia* "begins with a severe and usually protracted chill, followed by a rapid rise of temperature, 103° to 104° F., a strong, full, but rapid pulse, soon showing evidence of embarrassed cardiac action. There are also present pain near the nipple, aggravated by pressure, breathing, or coughing; shortness of breath, the number of respirations increasing to 40, 50, or more a minute; disturbance of the ratio between pulse and respiration; and cough, at first short, ringing, and harsh, followed by a scanty, frothy, mucoid expectoration. The sputum soon becomes transparent, viscid, and tenacious, changing about the second day to the familiar rusty sputum. The quantity is increased and a yellow color is assumed as the discase advances. The prostration is pronounced. The face is flushed, especially over the malar bones. The lips are more or less blue and herpes may be observed. Epistaxis, headache, sleeplessness, and gastric disturbances are common. The tongue is coated, the appetite is impaired, and there is constipation. Delirium is sometimes present. The urine is small in amount, highly colored, deficient in chlorides, and often slightly albuminous. The blood shows evidences of leucocytosis. The fever usually reaches its maximum within twenty-four hours and continues high, with diurnal remissions, until the fifth, seventh, ninth, or eleventh day, when a crisis occurs, and within twenty-four hours all the symptoms are lessened, the fever absent, and convalescence is established. Occasionally, the termination is by lysis."—(Hughes' *Practice of Medicine.*)

Indications for aspiration in acute serous pleurisy: When the heart is much displaced, when the heart's action is seriously interfered with (as evidenced by cyanosis dyspnea, or marked irregularity), in one-sided pleurisy when the dulness is as far up as the second interspace, in bilateral cases when the dulness extends about halfway up the thorax, when the effusion is not absorbed after the temperature has been normal for about a week. Some authorities would aspirate in every case where the effusion is marked (about two quarts).

3. *In carcinoma of the pylorus:* "Pain in the epigastrium, which gradually increases in severity, and discomfort after food, which later leads to vomiting, are the early symptoms. Blood is vomited in the later stages. The steady wasting of the patient, the presence of blood, and the absence of free hydrochloric acid in the vomit, are signs which point to malignancy as against gastric ulcer. Sometimes a tumor can be felt through the anterior abdominal wall. The stomach should be inflated to find out its exact size; the vomit should be examined for hydrochloric and lactic acids, sarcinæ and cancer cells. A tumor moving with respiration may possibly be felt, but the typical signs of pyloric obstruction are present—viz., the stomach becomes dilated; splashing occurs when the patient is moved, owing to the accumulation of fluid; a large amount of frothy fluid and decomposing food is vomited about every two days; and marked wasting occurs. In the later stages ascites occurs from pressure on the portal vein, jaundice from pressure on the bile-duct,

and edema of the legs from pressure on the vena cava." —(*Aids to Surgery.*)

Jaundice in gall bladder disease. Jaundice is generally obstructive, and means that at some point in the bile ducts there is an interference with drainage, *e.g.*, an infection which causes swelling of the mucous membrane and reduction of its carrying capacity either from within the lumen of the duct or a mechanical obstruction. . . Jaundice of itself has nothing to do with gall stones in the gall bladder. . . The more common sources of obstructive jaundice are inflammation of the gall bladder with or without stone, penetration of the infection through the gall bladder or the cystic duct to the peritoneum, stones in the cystic duct, stones in the common duct, carcinoma of the gall bladder.—(From Keen's *Surgery.*)

4. In typhoid fever, the *temperature* generally shows "during the first four or five days a daily increase of 1.5° to 2° F., and a morning remission of from 1° to 1.5° F., producing what is spoken of as the step-ladder course of the fever. The temperature usually reaches its maximum on the fourth, fifth, or sixth day. Then follows the fastigium, which lasts usually from ten to fourteen days, and during which the temperature is more uniform and of the continuous type, the morning temperature being 102° to 103° F., and the evening from 103° to 104° F., or higher. In ordinary cases toward the end of the fastigium (thirteenth to sixteenth day) the temperature becomes remittent, and the evening rise shows some tendency to be less marked. At the end of the fastigium (sixteenth to twenty-first day) the temperature is usually intermittent; the morning temperature approaching if not quite reaching the normal, and the evening temperature being 101° to 101.5° or 102° F. Gradually the evening temperature also becomes normal."

The *pulse* "is usually increased in frequency, though not proportionately to the fever. During the first week it is less than 100 as a rule; in the second week it commonly fluctuates below 110 and becomes dicrotic (characteristic). With the progress of the disease there is increased frequency of the pulse (130 or more sometimes), which becomes running or thready.

The *blood* shows a leukopenia (except in complications and after a cold bath when a temporary leucocytosis is observed), the large mononuclears are increased and the polynuclears decreased; the blood serum agglutinates the typhoid bacillus; during the latter half of the disease anemia develops.

The *skin* shows a characteristic roseolous rash from the seventh to the ninth day; it consists of isolated, circular, slightly elevated macules or maculopapules about 2 to 4 mm. in diameter; they are found on the trunk, especially abdomen and lower chest; they disappear on pressure, and reappear on removal of the pressure; they occur in crops, each spot lasting four or five days; sometimes there is a fine desquamation; loss of hair and edema are often present.—(From Kelly's *Practice of Medicine.*)

5. *Hematuria* may be due to disease or injury of the urethra, prostate, bladder, ureter, kidney, or to general disorders such as hemophilia, scurvy, infectious diseases or leukocythemia. In urethal troubles, the blood is generally pure and unmixed; in prostatic disease and tumors, it is an early sign; in bladder disorders the blood and urine are not intimately mixed, and the blood may escape at the end of urination, and microscopic examinations may show bladder epithelium; in diseases of the kidney, the urine is smoky and is intimately mixed with blood and may contain clots and casts and renal epithelium. A cystoscopic examination and catheterization of the ureters may help to differentiate vesical and renal hematuria.

The main conditions causing hematuria are: Trauma, calculus, tumors, ulceration, foreign bodies, parasites, inflammation, tuberculosis, and other infections in any part of the urinary tract.

Criteria indicating improvement in a patient with acute nephritis: "Favorable signs in the early stage are an increase in the quantity of urine and a diminution in the edema; in the later periods, diminution in the albumin, blood and formed elements in the urine, and a definite diuresis. . . Epithelial cells and free blood corpuscles become less numerous, and epithelial and blood casts are gradually replaced by the hyalin and granular varieties. . . Prognosis must always be guarded."—(From *Index of Prognosis.*)

6. *The effects of acidosis in diabetes mellitus,* are: Headache; lassitude, restlessness; dyspnea (at first inspiratory, later both inspiratory and expiratory); pulse small, frequent and of low tension; cyanosis; fruity odor on the breath; albumin and casts in the urine; coma; and death.

Prognosis of diabetes mellitus: This is bad in children and young people; as a rule, the later in life the disease begins, the better is the outlook; acidosis and coma are very serious. Joslin sums up the matter thus: "The presence of obesity, a favorable heredity, an early diagnosis, or the history of benign diabetes of several years' duration with gain rather than loss in tolerance, the retention of body weight, are good prognostic signs, but a placid, cheerful, courageous disposition, inherent or acquired, is fully as important."

7. *The etiology of Hodgkin's disease* is unsettled. It has been attributed to tuberculosis; it generally occurs in males, and chiefly between the ages of twenty and thirty; lymphatic disturbances and leukemia have both been noticed, but whether there is any causal connection between Hodgkin's disease and these conditions is not known.

Characteristic clinical symptoms of Hodgkin's disease are: Painless enlargement of lymphatic glands, generally beginning in the neck and remaining unilateral for some time; later, axillary, thoracic, inguinal and abdominal glands may become involved; secondary anemia, with diminution of hemoglobin and red corpuscles and a slight leucocytosis; pressure symptoms, with fever, emaciation, cachexia; pigmentation of the skin.

8. *Angioneurotic edema* is a condition characterized by localized edema of the skin and mucous membranes; it is transient, and is said to be a vasomotor neurosis causing increased permeability of the blood-vessels. It may attack the face, trunk, or limb; redness, itching, and pain may occur; and dysphagia, nausea, vomiting, and diarrhea may be observed if the mouth and pharynx and digestive tract are involved. Recurrences are common.

Raynaud's disease is a condition characterized by localized gangrene, asphyxia, or syncope due to vasomotor disturbances causing constriction of the peripheral arterioles; these lesions are generally symmetrical.

9. *Initial or pre-ataxic signs of tabes dorsalis:* Loss of knee jerk; paresthesia, such as numbness in the feet; lightning pains over body or legs; girdle pain; Argyll-Robertson pupil, diplopia, vertigo; loss of bladder control, or retention of urine; diminution of sexual desire; uncertainty in walking.

Visceral symptoms of tabes dorsalis: Painful "crises," such as gastric crises (severe epigastric pain with retraction of same region, vomiting, hiccough, restlessness laryngeal crises (due to spasm of laryngeal muscles, with cough and collapse); intestinal crises (with colic, rectal tenesmus, and diarrhea). Other crises are renal (with scanty urine and albuminuria), and bladder, cardiac, and bronchial crises.

10. *Acute chorea in children* occurs most frequently in girls; rheumatism is considered a cause; other causes assigned are neuropathic heredity, fright, reflex irritation from digestive tract or nose, poor hygiene, excitement, overstimulation at mental work, such as school competition, and various infections.

Treatment: Removal of cause, if possible; sane methods of education; proper food hygienic surroundings, and rest; salicylates, Fowler's solution, bromides, and strychnine are the drugs most frequently employed.

11. *Clinical symptoms of congenital syphilis:* These appear within the first three months; the child has an atrophied appearance, looks like an "old man"; has snuffles, relaxed and yellowish skin, weak voice and muscles, necrosis of nasal bones with depressed root of nose; there are fissures at the angles of the mouth, a copper-colored erythema on buttocks and inner sides of thighs, or palms or soles, and various other skin lesions; there are mucous patches in mouth and condylomata near the anus; the bones are thickened, and osteochondritis and craniotabes are observed; the liver and spleen are enlarged; later, Hutchinson's teeth (notched

upper central incisors), keratitis and iritis, nodes on the long bones, and synovitis may be seen.

By the *late manifestations of congenital syphilis* are understood those signs which appear at about the period of the second dentition or at puberty.

12. *Pellagra* has been attributed to: An intoxication caused by a parasitic growth on corn; an intestinal mycosis occurring from corn and an offending microorganism; an infection, and various parasites have been reported as found in the blood and organs; the action of the sunlight; unsanitary methods of sewage disposal; dietetic faults, especially to a deficiency of fresh protein. This last is Goldberger's view and is the popular one at present. Goldberger believes that pellagra may "be prevented and even eradicated by substituting a mixed, well-balanced, varied diet for the restricted, one-sided diet so common in pellagrous communities."—(From Rosenau's *Preventive Medicine and Hygiene.*)

13. *Clinical forms of plague* are: The bubonic, the pneumonic, and the septicemic.

A *typical case of bubonic plague.*—"After a period of incubation of from three to seven days the disease may set in quite abruptly, or after a prodromal stage, in which malaise, giddiness, mental hebetude, and pains in the back and limbs may be present. With the onset of the attack the effects of the toxemia upon the nervous system are the most striking. The patient has a pale, drawn, anxious countenance, with injection of the conjunctivæ toward the inner canthus. The speech is thick and difficult, the gait is staggering, so that, with the stupid mental state and tendency to wander aimlessly about, one has the symptom complex of an alcoholic intoxication. After a few hours, or within a day, the fever begins to rise rapidly and is often associated with shivering attacks. The face now becomes hot and flushed, the conjunctivæ markedly injected, the pupils dilated, and the eyes rather staring. The temperature is, as a rule from 102° to 104° F., occasionally higher, with a tendency to rather marked remissions and, on the whole, of great irregularity of the fever curve. The pulse is rapid and shows early indications of the extreme toxic effect exercised upon the heart. Cardiac weakness is a marked feature of plague. About the second or third day the development of an extremely painful bubo practically gives the diagnosis. About 70 per cent. of these buboes are of the inguinal region, the femoral glands being more frequently invaded than those above Poupart's ligament. The axillary glands are involved in about 20 per cent. and the submaxillary and cervical ones in from 5 to 10 per cent. of cases. As the case progresses the anxious countenance gives way to one of apathy, the control of speech and cerebration becomes more and more impaired, and the patient may go into a typhoid state."—(Stitt's *Tropical Diseases.*)

Prophylaxis consists in destruction of the fleas and extermination of the rat. The rat's food must be stopped; garbage must be protected; houses, walks, sewers, stables, and other places must be repaired and cemented to keep rats out; ratproofing of houses, etc., must be done thoroughly; concrete and galvanized iron are recommended. On ships sulphur dioxide may be used. Haffkine's prophylactic has been used as an immunizing agent; Yersin's antiplague serum provides a brief passive immunization.

Poland and French Science.—A volume has been written by a young Polish scientist with this title which is noticed in *Le Progrès Médical* for June 14. It is intended to show that Poland obtained its intellectual development chiefly from France. When the former country was converted to Christianity in the tenth century it was French monks from the cloister at Cluny who were the first missionaries. From that time distinguished Poles were educated in France, especially in letters and arts. In this connection it is stated that French physicians likewise attracted many students from Poland. French military officers supervised the organization of the Polish army. Many distinguished Poles settled in France and attained high honors, some of them dying for France on the field of battle. The following distinguished names of Poles are associated with present day medical science—Babinski, Kirmisson, Potocki, Danysz, and Mme. Curie.

Miscellany.

Death of Golgi.—According to an article in *La Riforma Medica* for June 28, Camillo Golgi died recently at the age of 75. He was widely known in two different fields—histology and malaria. While the histology of the nervous centers goes back to the time of Stilling in 1842, it was not until 30 years later that Golgi, by means of his new stain, first obtained a representative view of these tissues. Like Koch, he was far from a medical center when he devised his celebrated technique (black stain). He was known at the time only as a graduate of the University of Pavia in 1865 and an interne in several clinics at the St. Matthew's Hospital. He studied the use of the microscope in the Pathological Laboratory in that city, the first to be established in Italy—in 1861, under Professor Bizzozero, himself then a young man. From the first he specialized in the histology of the nervous centers. The excellence of his work was soon known all over Europe. His first experiment at Sienna in 1876 was soon followed by the chair in his alma mater of Professor of Histology and General Pathology. When Laveran, as a comparatively unknown man, required an expert of standing to stand for his discovery of the hematozoon as the cause of malaria, it was Golgi who became his sponsor, and Golgi continued to be identified with the parasitism of this disease from then on. In 1906 he was awarded the Nobel prize for science.

Antonio Grossich.—This surgeon, famous for his recommendation to use iodine tincture as a disinfectant of the operating field is not a Slav but a resident of Fiume, that much disputed "prize" of war. In the *Riforma Medica* for May 3 he receives an appreciation at the hands of Paolucci. He is descended from an old Istrian family which goes back in documentary exhibits to 1635. From these it appears that the name was originally Grossi. When Istria was overwhelmed during the Napoleonic wars the land of the Grossich family, then in charge of the doctor's grandfather, seems to have been under the direction of Massena, Napoleon's marshal, who maintained the most cordial relations with the owner. The father of the subject, an entirely Italianized Istrian, was active in the government of Fiume while the mother was from Friuli. The subject of the sketch was born in 1849 at Fiume and graduated in medicine at Vienna in 1876. For the next ten years he was devoted to operative surgery. Albert being one of his masters. In 1886 he returned to Fiume and specialized in surgery, gynecology, and obstetrics. His renown came to extend over Istria and Dalmatia. His method for sterlizing the operation field with iodine now in general use was first published in 1908, and one year later he read a paper on the subject at the International Congress at Budapest. When Italy entered the war he seems to have been interned by the Austrians. His hospital, which was a feature of the daily life of Fiume, seems to have been abandoned for a time. Grossich's services in teaching the antiseptic properties of iodine, will rank him high among the surgeons of the twentieth century.

SOUVENIRS OF AN OLD NEW YORK PRACTITIONER OF MEDICINE.

BY BEVERLEY ROBINSON, M.D.

NEW YORK.

IN going back to early days, I well remember how Dr. Charles D. Meigs and his son, John Forsyth Meigs, the elder Pepper, Drs. Gross, Mitchell, Da Costa, were regarded in Philadelphia, by their patients. They were respected, beloved, and obeyed, with absolute confidence in whatever they advised. Later, when I started in practice in New York, I remember how Alonzo Clark and Willard Parker were regarded: the former the summit in medicine, the latter equally renowned in surgery.

They passed and Drs. Markoe, Sands, Peters took high places in surgery, while the elder Flint, Metcalfe, Loomis, Delafield, Janeway, came to the front in medicine. Markoe, Sands and Peters, were replaced by Bull and McBurney. All these "good men and true" are gone to the silent land of the majority, but they left their impress upon the few of us who still remain. If we have not been able to equal them, we have tried to follow in their footsteps of high thinking and doing; of rectitude in thought and purpose.

These noble men had their distinctive qualities, or peculiarities, which belonged to them personally and served to individualize them, just as their presence and bearing did.

Dr. Metcalfe was the charming, genial host, always pleasant, attractive, and cracking his witty jokes frequently. Then too, he was the skilful, sympathetic, kind physician. I remember well, when my younger brother was taken ill in my office with scarlet fever, how he came to my help and soon got me out of trouble. Thanks to his kind intervention, the patient was soon transferred to a private room in the Presbyterian Hospital, where he received every care and attention. Except for Dr. Metcalfe's strong and winning personality, I feel my brother's reception at the hospital would have been surely negatived.

At that time, Dr. William M. Polk was Dr. Metcalfe's associate in practice and did much of the onerous work, day and night. On one occasion, when seated alongside Dr. Polk, I asked him how he amused himself. He answered, I do not; I have never found time and I do not know how. Then he added: Robinson, I fought on the Southern side in the war of the States, as a private soldier at one time, and I tell you the life of a conscientious, successful general practitioner of medicine, is more trying and arduous. Later in life, seated on the piazza of the Inn in the village, where I have my country home, Dr. Polk, then distinguished, repeated his remark. I would add that I felt then and later, the truth of his statement. Indeed, I know of no profession, other things being at all equal, in which the life of the conscientious, successful practitioner, is so exacting and irregular. Here it is, that the man is made, who becomes like refined gold or the veriest dross. It is in a way, a furnace testing. But in those days, loyalty and devotion to the family physician still repaid his personal self-sacrifice and he was glad to give it. The pecuniary return to him was relatively meagre at times, and his outlay of strength and anxiety was very great, but with it he had the greatest of life's compensations—the consciousness of duty well done.

To-day, with the overgrowth of modern specialism, the general practitioner, as formerly met with in our cities and towns, has almost disappeared. Will he ever return? I believe he will, and when he does mankind will be purer and better, mentally and bodily.

The first year I was in practice in New York, I became assistant to Dr. Alfred L. Loomis. Loomis was a great practitioner, with a clear insight into disease and how to manage it. His classes listened to him eagerly and believed in him thoroughly. He was a forceful, clear speaker—and why? Mainly because he first read and informed himself fully as to his subject and then allowed the spirit and enthusiasm of his class to inspire his words. Loomis in this way usually said what was correct, just as his diagnoses were frequently sound. Occasionally, he tripped up because of his too positive way of teaching. He did not speak of exceptions. These, he affirmed, students would learn later and the better way to teach them was to state facts baldly and without exceptions.

The elder Flint was the antithesis of this. He mentioned exceptions; he felt *that* was the correct way of teaching. Flint was a true medical philosopher. Then, too, he knew medicine thoroughly, and believed much in the self-limitation of acute disease. He had only a moderate amount of faith in the efficacy of drugs. He had two remedies, however, of which he was very fond: One was iodide of potash; the other, Huxham's tincture of bark. Whenever a modifying agent was required, he gave the former; when a tonic was indicated, he gave bark, usually, with tincture of nux vomica. In consultation, Dr. Austin Flint was a model. He listened to the attending phy-

sician's account of the patient. He then examined him. Afterwards, he suggested what he had to say in the way of treatment, or change, though rarely, in diagnosis. When asked his opinion about the patient by family or relatives, he waved them courteously aside, referred them to the family physician, and left the house with a smile and a bow to all. Flint's dignified appearance was calculated to inspire confidence and kind feeling. His manner was genial and courtly. Loomis was somewhat brusque and scarcely, as a rule, what one would call affable. With his patients, however, even the wealthiest and most prominent, he laid down the law and it was implicitly obeyed.

When I left the University as his assistant and went to Bellevue Hospital Medical College, as lecturer, he simply said to me, on one occasion when I was breakfasting with him at a medical meeting out of town: "Robinson, you made a mistake. If you had remained with me, you would have been further advanced." Perhaps so; I doubt it.

As a lecturer at Bellevue Hospital Medical College, I followed the handsome, courtly William H. Van Buren. He had won renown as a distinguished surgeon in his specialty and had served with honor on the Sanitary Commission during the war of the States. I said to him one day as I finished my lecture and he was about to go before the students;—"How is it, Dr. Van Buren, you can keep up your interest in talking to students?" He answered simply, "I feel I know something which I want to tell them." On another occasion, during the summer when he was having his vacation, I called him in consultation about an important and dangerous case. After the consultation, I asked him the amount of his fee. He answered, "Nothing." I insisted. "Well! if you will have it so, call it $25." In those days, fees were one half, or less than they are to-day.

In the days of Meigs, father and son, they were far less. Dr. Charles Meigs never sent a bill. He considered it derogatory. He would accept an honorarium, if sent to him. How then did they live? Living was cheaper. They lived laborious lives and gave themselves wholly to their profession, and had few or no amusements, not even the theater, or a game of cards or billiards. They were men of good, often high social position, before they became doctors and inherited some money from their parents. Besides, they entered the medical profession with a high ideal of its nobility and would do nothing to lower it. To ask or exact large fees was to make a trade of it and to lower it. They wished to do, and did, everything to promote the well-being and cure of their patients. There was no service, with this intent in view, which seemed to them beneath their dignity or moral obligation. Hence, they became models to all.

A notice of John Forsyth Meigs after his death in Philadelphia, speaks of him as a "gallant, modest, unselfish, blameless, civic hero." And it was true, as I can affirm. I have had his photograph on my mantel for many years and beneath it have written "the good physician."

When I first came to New York, I brought a letter of introduction from Dr. William Pepper, of Philadelphia, to Dr. Abraham Jacobi. Even at that time, he was spoken of as a mine of medical lore. He died at an advanced age. To the last, he worked for every good and noble cause. His life was, indeed, most beneficent.

Every one heard of Dr. Jacobi and, invariably, in terms of highest esteem. He stood always for what is highest and best. His books, his articles, his remarks before medical societies, were ever filled with wisdom in regard to medicine. He was a very valuable, patriotic citizen; indeed, a splendid example to all. During the late world war, although of German birth and parentage, he was ever a loyal American. To his adopted country, he affirmed he owed much and he repaid it by whole-souled devotion. I am proud to have numbered him among my friends. On many occasions, he showed me sincere affection.

In the early days of my connection with Bellevue Medical College, the professors were a fine lot of men, not merely because of their works, but also on account of their appearance. Flint, Van Buren, Barker, Lusk, Doremus (one armed) and, previous to my time, George T. Elliot, by their height, bearing, vigor, dignity, would have been marked men in any assembly.

Sands was then the surgeon at his zenith, to whom all New York surgeons looked. Always they wished to know what he said or did in any difficult or obscure case. He had the rare gifts of great skill and excellent judgment.

Dr. T. M. Markoe, also a prominent surgeon and practitioner, was very genial and told good, entertaining stories; he was a faithful attendant of the Rev. Dr. Hall's church. On one occasion when in attendance upon a distinguished lawyer, recovering from typhoid fever, he made daily visits, told a mirthful story, had further a little chat, felt the pulse, looked at the patient and left without writing a prescription or ordering anything specially. The patient tiring somewhat of this because he thought the bill would come ultimately for these visits and not seeing their practical utility, said one day to Markoe—"Dear Doctor, I enjoy your visits of course, but I do not see precisely their curative value to me." Foolish, shortsighted, as many patients are. Markoe was watching, but surely would have prescribed if he had seen the need of it, or had not rightly recognized that nature was doing better work than he could at the time and required no useless, or rather harmful, interference.

This same patient once said to me that he thought the real function of a doctor was to take foreign bodies from the eye and to give hypodermic injections of morphine for pain. He thought it was funny. It was certainly apt, many times. After Sands and Markoe died, McBurney and W. T. Bull were the two peers in surgery, not mentioning our still living and venerated Robert F. Weir.

McBurney will always be widely known for his "point" in appendicitis, and also for his mature wise consideration of a case, both as to surgery and medicine. He once remarked, in the discussion of a case, that in his judgment it required as much thought to prescribe a dose of

medicine as to do an operation and it was equally important.

Dr. William T. Bull, of whom I have never yet met the peer, was to me the ideal of what a surgeon and a man should be. He was handsome, self-contained, skilful, and most kind and considerate always. He was most successful, as he richly deserved to be. I could tell many stories about him, illustrating the different sides to his remarkable and winning personality. I shall mention a few. On one occasion I went to him with a patient who had dislocated her lower jaw. I had made ineffectual attempts to reduce it. Dr. Bull also failed more than once and then happily succeeded. I watched him closely and said: "Bull, I do not see that you did differently from myself; I presume you are stronger." He simply smiled and said nothing. Later, at a "spread" given after a medical meeting, I happened to hear Bull say to Dr. McBurney, "and the joke of it is, I had never reduced a dislocation of the jaw before." Of course, I turned to him and said, "You are a sweet one." On another occasion I called at his office and asked him to see an important case with me. He said, "Really, Robinson, I cannot to-day." "Well!" I said, "call it to-morrow." "No," he said, "not to-morrow—I cannot. I am going out of town this afternoon." "Where are you going?" "To Newport." "What to do?" "To operate." "Well! I suppose you will get a big fee." "No, I do not expect to. I shall operate upon an old friend." "Is it serious?" "No." "Why do you go?" "He wants me." There is the picture of the man. Office full of patients. Making money inside and outside the office, crowded with business and every one wanting him. He gives it up on the call of a friend, takes two nights on the boat and passes a day at Newport, working, all for nothing but to do a kind, generous act. I saw him in his last illness. He was in bed, his neck bandaged up. He knew he had a fatal disease. As I came in, he said. "How are you and how is your wife and how are the children?" Never a word about himself. As I left him, I said, "I wish I could do something for you." "Ah!" he said, "I don't think you can, unless you can send me some 'blood and thunder' novels I have not yet read." At that time, he repeated the Lord's prayer like a little child, word for word, after his faithful and devoted nurse, who had been superintendent of his private hospital. When my boys were young, he would say to them, "Now, boys, the circus is in town, I presume you would like to go." Promptly he bought tickets for a box and sent them. Of course, my boys and their invited friends were overjoyed. I could go on and tell many stories, all of which simply show what a charming, lovable personality Dr. Bull was. If he had been at the front lately, I am sure he, too, would have brought home a noble record of brave, glorious deeds.

Dr. Francis Delafield was certainly a very distinguished professor and consultant. His great work on pathology has reached many editions. He had his strongly marked characteristics. One was that he was usually sure his judgment in a case was correct, and he did not suffer doubt of it with any evident satisfaction. Still, to those who knew him well, Dr. Delafield was urbane and hospitable, but his manner was ever sedate and quiet—and he rarely committed himself to a joke. He said on one occasion, although he was a sincerely religious man, that he thought a clergyman should limit his vocation to preaching in the pulpit and should not extend his ministrations to visits to his congregation, else he not infrequently lost his beneficial influence To Dr. Delafield's outspoken fairness, I feel I owe my being one of the original members of the Association of American Physicians. He stood up for me squarely, when one of my friends from boyhood days failed to accord me his support. Dr. Delafield was fond of good dinners and good cigars. Dr. Janeway cared little, or not at all, for either. Delafield and Janeway were mutual friends and admirers. When Delafield was ill, Janeway took care of him. When Janeway had pneumonia, he relied upon a young doctor of medicine, from one of his classes. He gave the orders and the doctor obeyed. Together, they pulled him through all right. In addition to a few simples in the way of nutrition, Dr. Janeway took frequently moderate doses of old brandy. Upon this remedy he placed chief, indeed, sole reliance. He also believed in the efficacy of time, if you could last long enough. And he did.

Dr. Edward G. Janeway was my stand-by in all matters medical. I believed and trusted him absolutely. He had rare diagnostic skill. He had a fund of common sense; he never went off on tangents, he was absolutely reliable. He was not really fond of anything other than medicine. That he loved and was most devoted to it. He rarely made any mistakes. He did not believe much in the utility of drugs except those that are simplest and best known. Of these he would give small doses and in taking care of me on one occasion, he said, "I would take that myself; I don't think it will hurt you." Although Dr. Janeway reached the top of the ladder and was consulted far and wide, he never took advantage of his position to ask exorbitant fees. He was always moderate and just.

To-day, I know of no one who takes his place in medicine; to-day, I know of no one who takes Dr. Bull's place in surgery in civil practice. We have, I am proud and happy to say, now in the midst of us more than one eminent surgeon who has won great and deserved renown at the front, during and after the terrible battles of the late war. Glory, and rightfully, be theirs!

Among the prominent specialists I have known well, were Dr. D. B. St. John Roosa and Dr. C. R. Agnew. They were both prominent oculists; they were both very successful in making money. Neither of them, however, left money to any extent. They were most generous in all good works and thought little of accumulating—maybe too little. They both figured in a public way and were strong republicans.

Dr. Agnew was the head and front of the Manhattan Eye and Ear Hospital; Dr. Roosa was President of the Post-Graduate Hospital, which he greatly helped to found and to put on a firm foundation by reason of his gifts, his influence, and his arduous work in its behalf. Dr. Agnew's

work and doing for the Manhattan Eye and Ear Hospital was not unlike that of Dr. Roosa for his beloved institution. At the time that both these men were prominent in New York, publicly and before the profession, the great fight took place between those who upheld the old code and those who favored the new code. The old code men would not hold consultations with the homœopaths; they regarded them as being, in a way, charlatans. The men who maintained the new code doctrines felt that consultations should be held with homœopaths when their services were requested and seemingly desirable. Here then was the split and the fight was long and bitter. The two Flints, father and son, were old codists; Agnew, Roosa, and Barker were new codists. Now fortunately, this antagonism against worthy men of the homœopathic school no longer exists, or if so, in minor degree.

T. Gaillard Thomas, Emmet, and Sims, were the reigning gynecologists. Thomas was the readiest speaker among them and certainly was especially gifted in this way. Emmet was particularly renowned for his skill in operating on vesico-vaginal fistula. Sims had also won renown abroad for this same operation. He was also beloved by the French for his great services during the Franco-Prussian war of 1870-71, as head of the American Ambulance. Sims was a most engaging and charming personality. These three men were identified with the Woman's Hospital and gave it its well merited renown.

The bronze statue in Bryant Park shows what the esteem was for Marion Sims in New York.

Fordyce Barker was prominent as an obstetrician in the hospital and among the wealthy. He was the ordinary family physician of the Astor and other well known families. Barker was ever most genial and whole-souled. On one occasion when a dealer in wines was vaunting the great value of California wines, he simply, after a few moments listening, put his hand on the man's shoulder and said with his raucous voice, "My friend, French wines are good enough for me." I, with not a few others wished to know what was the cause of Dr. Barker's hoarse voice, but we never did and he never told us. Barker was not a surgeon and did no operative work in gynecology, as Thomas, Emmet, and Sims did.

In later years, his associate, Dr. A. A. Smith, did much of his practice, obstetrical and general. Dr. Smith became Professor of Medicine at the University and Bellevue Hospital Medical College and was an admirable, all around general practitioner. He also, was a devoted friend and never failed to make one thoroughly realize it in time of need. I had for him the greatest esteem and personal friendship. This friendship was also, extended very warmly both to Drs. Roosa and Polk.

Dr. Lewis A. Sayre was perhaps a little brusque and rough at times, but truly "a rough diamond" —and kindliness and true manliness were always beneath the surface. Sayre was a practical genius in orthopedic surgery and in his day spinal curvature was greatly helped by his braces, and especially Pott's disease by the suspension and jury-mast he surely brought into vogue if he did not invent.

Dr. William T. Lusk, who filled the chair of Obstetrics most ably after Dr. Barker had resigned, was a very attractive and pleasing man. He had a most kindly and cheery disposition. Professionally, he was a success in the hospital wards and at the bedside of his private patients. He was as modest, as he was talented and skilful. His record during the Civil War was most praiseworthy. He saw much active service and did it with great credit to himself and country. Very few of us knew about it, until his sons told us in the life of their father.

Dr. James McLane also, professor of obstetrics and a skilful practitioner in his specialty, to whom we owe the Sloane Maternity Hospital, by reason of his influence with his wealthy patients, the Sloanes and Vanderbilts, was known widely among his colleagues for his clever, amusing stories, which were the delight of the New York Medical and Surgical Society and helped to enliven very much their "bang up" suppers. I shall never forget one occasion when I was with a near relative whom Dr. McLane had just confined and who was suffering from pronounced nephritis. He had given a fairly large dose of jaborandi to act upon the kidneys. Instead of acting thus and beneficially, it unfortunately produced rapid edema of the lungs with profuse, frothy expectoration. The patient became rapidly unconscious and died after repeated uremic convulsions. Dr. McLane was much impressed and even shocked and, I was told, often narrated his sad experience to his class at the College of Physicians and Surgeons.

Dr. Francis I. Kinnicut was a great enthusiast in medicine and never tired of searching deeply and thoroughly into every matter of interest pertaining to it. His sudden and untimely death at a meeting of the Practitioner's Society was severely felt by many friends.

Dr. George F. Shrady, longtime editor of the MEDICAL RECORD, was full of quaint, adorable humor. He made me laugh almost before he began to speak. When near death, I saw him in consultation with his family physician. He looked up at me as I put my hand on his abdomen and said, "Bev, I don't want to die." As he said it, I thought, despite his condition, there was a merry twinkle in his eye. Shrady knew the power of mirth he had over me. At the time, I could have laughed and cried at the same moment. Fortunately, I did neither. Dr. Shrady took care of General Grant during his last painful illness and was all that a man could be to his illustrious patient. General Grant's last illness is faithfully reported in a monograph that Dr. Shrady gave to a few friends.

Dr. George L. Peabody was for many years professor of therapeutics at the College of Physicians, and he filled the chair with marked distinction. I always hoped he would be made professor of practice, for which he was eminently fitted by his clinical experience at the New York Hospital, where also he had been pathologist for many years. Dr. Peabody, while pathologist, practically made its museum, later given away, I believe, to the College. Dr. Peabody was ever, aside from his medical knowledge, a gifted, accomplished, and refined

gentleman. He loved all that was cultivated and attractive in art and letters. He was a most agreeable and hospitable host. He had a keen sense of mirth and jollity, deep down in his composition. Never very robust, in the later years of his life he gave up practice, which was largely consultant. He never cared much to do general practice and found it hard to buck up against its evident drawbacks, as the general practitioner was less valued by an ignorant community, who became imbued with the modern fad of exclusive specialism, much to their own disadvantage. Dr. Peabody died suddenly, in Newport where he resided, of angina pectoris, in 1914. Take him all in all, he was a thorough-bred gentleman in thought, word, and deed. To his friends he was a great loss. We shall rarely meet his like again.

Dr. Henry F. Walker was one of the most beloved of New York physicians and rightly so. His manner was charming, sympathetic, and affable. He had had a very wide experience in general practice and his devotion to his patients, even in advancing years, was untiring.

During many years he was the associate of Dr. T. G. Thomas and attended all the cases of general practice that came to them, and also the obstetrical cases. Dr. Walker was full of good works, aside from those of his profession. His generosity was very great and all worthy objects appealed to him. He died well on in years, in 1917, regretted deeply by all who knew him.

One of the pleasant reminiscences I have of the Bellevue Hospital Medical Faculty is the annual dinner where they were all united and some of us younger ones were guests. I recall vividly James R. Wood, Doremus, the two Flints, and Isaac E. Taylor. "Jimmie" Wood, as he was affectionately called, was a dapper, fresh-looking, well clothed little figure—always with a flower in his buttonhole. He it was who said the "vox populi" had their eyes on the student; he it was who could amputate a limb most dexterously and almost in no time. Taylor could easily apply forceps at the upper straight, or do a version in a difficult case when to others it would have been most difficult. I can well remember also, his medical acumen when in the case of a patient after childbirth, who had profuse, prolonged, weakening perspiration and quinine had been given fruitlessly, he gave relief very soon, with dilute sulphuric acid and infusion of roses. Despite Dr. Taylor's great skill and knowledge in obstetrics, he could not always speak in a consecutive, suitable way. This was particularly noticeable when he conferred the degrees upon the students as president of the faculty. Never twice consecutively, did he repeat the Hippocratic oath correctly. There were invariably changes, corrections, muddling. Of course, not a few present, students or guests, broadly smiled.

Another reminiscence of my early days in practice was my visits as attending physician to Charity (City) Hospital. I often went across the East River when it was full of thick ice, rowed by an employe who was not too sober at times; again I have been across in the spring or early summer, when the Sound boats came so near us at times, as to cause an unpleasant thrill at the thought of being run down. One Sunday afternoon I remember specially. The tide carried the rowboat down below the general hospital close to the hospital for smallpox patients. The house physician called to us to let him get aboard. We did so, but greatly to the consternation of a woman in the boat when she learned whence he had just come.

I could go on in this way for many pages and speak of other prominent physicians and surgeons, and often dear friends, who have left us, but I feel that it is well to stop. I hope my imperfect souvenirs may prove of interest to some still living, who knew those who are now, alas, with the silent majority. To the others, of a younger generation, they will serve to let them know somewhat what manner of men their predecessors were.

I felt somehow, for both, that in view of my age and antecedents, it devolved upon me to bring again to vision this brief retrospect of the good and true, in our profession—so well beloved and honored.

Will our modern and great advances in medicine and surgery make a nobler, finer set of men than I have tried to portray? I scarcely think so.

Peace and love to them all!

42 West Thirty-seventh Street

PITYRIASIS ROSEA.

By WILLIAM P. CUNNINGHAM, M.D.,

NEW YORK

CONSULTING DERMATOLOGIST, MISERICORDIA HOSPITAL; ASSOCIATE VISITING DERMATOLOGIST, CHILDREN'S HOSPITAL, RANDALL'S ISLAND.

Aside from its attractive title, pityriasis rosea possesses characteristics warranting the close attention of the general practitioner. The dermatologist rarely mistakes it; other observers often do so. Herein lies the advantage of acquiring a knowledge of its usual manifestations. It is of importance because of the errors of which it is the innocent occasion. It is a trivial affection, as a rule, giving rise to a very little annoyance except that of its unwelcome presence. Everybody objects to cutaneous eruptions whether they are accompanied by disagreeable sensations or not. The abnormal is disturbing and when it is visible it arouses the patient's anxiety out of all proportion to its actual gravity. Vain imaginings excite serious forebodings. If the practitioner is unable to reassure the patient, the mental disturbance is aggravated, and becomes the dominating element of the pathology. If he is able, however, to speak positively of the insignificance of the eruption, he will have cast out a devil. Doubt will give place to serenity and the resolution of the disease will be awaited with equanimity.

It is rare that pityriasis rosea comes to us with a correct diagnosis from the preceding observer. The treatment is so simple that if the diagnosis were established no assistance would be required. The eruption appears suddenly and usually without warning of any sort. There may be slight itching which attracts attention to the spot, but frequently this is lacking and it is the accidental discovery of the patches which gives the first intimation of any

abnormality. The usual lay opinion is that it is a "stomach rash." A laxative is taken, the diet is reduced, and developments hopefully awaited. Disappointment resulting and the area of involvement increasing, alarm drives the patient to the family physician. His glossary of cutaneous diseases containing just two words "eczema" and "lues" he bends his energies to discovering which it is. The victim is lucky if he hits on "eczema". On that hypothesis he may make a fortunate attempt at treatment. If, however, he becomes obsessed with the idea that it is lues, deplorable consequences may be entailed. A Wassermann test will be demanded, and the doubt created may never be completely dispelled.

The syphiliphobiac is a well-known psychological derelict. He wanders from physician to physician seeking ever new resolution of his doubts and ever distrusting the decision in his favor! He dreads that there may have been some confusion of names; some mixing of specimens; some fault of technique operating to invalidate his latest Wassermann test. "If he were only sure that everything is as it is represented! "He has learned in his voracious reading and insatiable cross examination of medical advisers that negative results of the Wassermann are not conclusive. This is an everlasting source of uneasiness to him. It arises like Banquo's ghost with incessant insistence, and will not down even after the most emphatic assurances of his delusion. It is indefensible therefore to hint at lues in any case where there is not strong evidence of its presence. We must not take the chance of setting afire a train of suspicion that may eventuate in monomania!

In order that such a deplorable contingency may be avoided it will repay the practitioner to familiarize himself with the manifestations of pityriasis rosea. It will be retorted that as the works on dermatology do not stress the possibility of confounding these with the manifestations of lues there must be little likelihood of its occurrence. But the books are at fault. Practical observers know that the blunder has been made many times by inexperienced clinicians and more than once by those of large experience! As stated at the beginning of this paper dermatologists rarely make it. That means that they do sometimes! Here is all the warranty needed to urge the physician to give heed to the picturesque lesions of this otherwise trifling dermatosis.

They are in the class of exanthemata. Corroborative of this is the occasional constitutional disturbance preceding the outbreak. This is slight and may be overlooked. A little elevation of temperature with soreness of the cervical glands, and perhaps an ephemeral pharyngitis, comprise the premonitory symptoms. The eruption consists of patches varying in size from that of a small papule to that of a quarter piece. The outline may be circular, oval, or irregular. The greatest number are oval. They are slightly scaly. Their color is pink at the periphery and fawn at the centre. Some are deeper hued, being red at the periphery and salmon at the centre. The scaliness may show itself only in a slight crinkling of the surface likened to that of cigarette paper. Or the epidermis may be turned up in a little cuff separating the darker rim from the shading centre. This is regarded by Walker as pathognomic of the disease under discussion. The opinion is probably correct as it is not found in other conditions at least with any uniformity. I have learned to rely upon it in situations where the other features of the eruption are not perfectly obvious. As occurs in all cutaneous diseases the typical is often obscured by irregularity of development or injudicious management. Circumstances which we do not understand, and cannot control, determine these variations. The patches seem in a more or less orderly way to follow the lines of cleavage of the skin. They show a tendency to form in festoons or loops curving outward and downward from the centre. When they are plentiful, this arrangement may be made out with tolerable clearness; when few, there does not appear to be any method in their disposition. Coalescence is effected when an area is crowded and the resulting figure may be gracefully quaint. The fluted edge with its delicate pink fading off into as delicate fawn adds greatly to its attractiveness.

It has been mentioned that cases occur which depart conspicuously from the usually softened tint of the ovoid lesions. The red of the periphery and the salmon of the centre form one well-recognized variation. Intensity of the morbid process may cause the evolution of papules appreciably elevated above the surrounding skin. These are of a darker hue and do not present the nuances characteristic of the typical cases. They are somewhat scaly and it is their appearance which has sometimes led to the embarrassing paradiagnosis of lues.

The situations favored by the eruption are the back, chest, and sides. When it is profuse it will spread to the neck and arms and downward upon the abdomen, buttocks, and legs. Occasionally whimsical in distribution as in appearance it will involve the limbs and avoid the trunk. The face is very seldom if ever affected. A curious incident in the development of the disease is the initial manifestation or herald patch. This is a large patch (larger by far than any that succeed it) situated usually upon the flank or abdomen. It is vividly marked with all the distinguishing characters of the typical lesion. It has been quite aptly compared by the French to a medallion. It may be several inches in the long diameter and is oval in contour. The most remarkable circumstance in connection with it is its long precedence of the full efflorescence of the established disease. This may be a matter of a week or ten days. The herald patch is frequently overlooked because of this hiatus. It is so situated perhaps that it does not attract the eye of the patient and there may be no subjective symptoms to draw his attention. This herald patch is one of the curiosities of dermatology. In an otherwise indecipherable cutaneous puzzle a trustworthy history of such a sequence of events would be decisive.

Pityriasis rosea occurs with equal frequency in both sexes. It is hardly ever seen in children. Ormsby puts the age limitations at fifteen and forty. Personal cleanliness does not seem to be a factor in the etiology. The unwashed dispensary patient is as common a victim as the scrupulously greomed private patient. In point of fact it is rather unusual to find pityriasis in the sort of person given to pediculosis corporis. There is undoubt-

edly a seasonal incidence of this dermatosis. It is more prevalent in the spring and fall than at other times. What this may indicate it is impossible to determine in the present state of our knowledge. We may reason that as nature at these periods is undergoing marked vegatative changes, the influence is extended to the human economy. This of course is of the vaguest, as we do not know that such an association exists. It was strongly maintained by the older physiologists and would appear to be supported by some very suggestive coincidences. For instance Crocker says that "Psoriasis is proverbial for its recrudescence in the spring"; and we are all aware of its recrudescence in the fall. Erythema multiforme displays the same periodic aggravation. Urticaria, being a close associate of the former, etiologically and morphologically, imitates it chronologically. Herpes zoster seems as strangely affected by the changing seasons. He who has given close attention to acne will discover that the spring brings exacerbation in many cases.

There is no question that spring is accompanied by a rather general disinclination to effort. We are all slowed up by it more or less. This has been denominated "spring fever" but there does not appear to be any of the concomitants of fever. Rather is there a sluggishness and hebetude, directly contrary to the activity of fever. Its source was supposed to be the liver; which was wont to be the scapegoat for almost every indefinable pathological syndrome. Now I am not of those who depreciate the opinions and practices of our predecessors, in the art of healing. It is customary to refer with a tolerant smile to the superseded doctrines of a past generation and plume ourselves upon the accuracy of our methods and the exactness of our information in this day of enlightened achievement. But are we sure that our pride is solidly grounded, and that our advance has been really so wonderful and our departure from the ancient creed so radical and wide? Are we sure that we are not more concerned with terms than with conditions? Are we not putting new labels on old bottles? If our predecessors believed that the liver was at fault in the circumstances mentioned and we believe that the trouble is with the internal secretions, are the two propositions actually opposed? If they maintained that the organ was not functioning properly and we maintain that its internal secretion is either excessive or deficient, have we advanced anything contradictory? Old-fashioned English was enriched with the word "splenetic", which conveyed the idea of ill-temper or irascibility. If there was not an adumbration of the modern doctrine of endocrinology in the minds of these acute observers, it was a marvelous coincidence that they should have stumbled upon one of the great facts of modern pathology! For if we substitute "thyroid" for "spleen" their case is complete. Their significant discovery (linking them up with the most recent investigators) was that an organ without a duct exercised influence over the physical and mental condition of the patient. It was valiantly defended also that the testicles were vitally concerned in the conservation of health and that sexual excess was detrimental in withdrawing too much of the testicular secretion from the body! In our highly specialized pursuit of scientific data we are much impressed with the importance of the gonads! The humors to which the elder pathologists ascribed disease, bear a pretty strong resemblance to the "hormones" of today! It is likely then that the conception of the influence of spring upon the health of the individual, was not simply aimless groping for an etiological explanation, but a vision "through a glass darkly" of the domination of the internal secretions! And this influence certainly exists! And is as certainly due to the interaction of the "humors" or hormones of the ductless glands!

This digression may be excused as an attempt to justify certain deeply rooted traditions fighting hard for survival in this day of scientific precision. These traditions were grounded in observations remarkably keen, considering the limitations of the investigators; and were supported and developed by close deductive reasoning. So that we are frequently astonished to find that some of our twentieth century "discoveries" are really the evolution of ideas originating in the analytical minds of our very attentive forbears!

While pityriasis rosea is subject to seasonal recrudescence, little or nothing is revealed thereby of its etiology. If the internal secretions are at fault the association is not manifest. In the somewhat turbulent outbreak of erythema multiforme the complicity of intestinal toxemia or susceptibility to a particular comestible is suspected and usually demonstrable. The adrenals, readily responsive to infection, retain the secretion that controls the blood vessels and we observe the peculiar phenomena of vasodilatation and lymph effusion. What limits them to circumscribed areas when there is the operation of a general cause, deponent sayeth not. Perhaps local irritation adds the element that completes the vascular paresis. Satisfying or not, this is the only explanation vouchsafed by current pathology.

In the language of the painter, pityriasis rosea might be compared to a picture of still life and urticaria and erythema multiforme to one of animated nature. Pityriasis rosea is not bumptious; it is not impetuous; it is not capricious. It is patient, placid, and plodding. It may select its location without apparent order or regularity, but once selected it sticks to it and does not disappear and reappear vagariously. Intestinal toxemia would seem to be excluded by these circumstances or at any rate "not proved." And yet to show the unreliability of that conclusion it is only necessary to point to the practice of eminent dermatologists in administering salicylate of sodium in this disease! Despite the arguments against their hypothesis they are confident that disinfecting the intestinal canal is of material advantage. Another designation for the affection is herpes tonsurans maculosus. Herpes would suggest a neurotic origin; tonsurans would suggest a parasitic origin; maculosus of course simply indicates the morphology of the patches. Both the nervous and parasitic origins are defended. Patients with the eruption are described as irritable and nervous. This may be an illustration of "mettant la charrue devant les bœufs" or putting the cart before the horse; because most patients who find themselves the victims of a persistent skin disease become much upset in consequence! The parasitic causation has not been proven or this dis-

cussion would be supererogatory. Yet from the contour and the scaliness of the lesions it bids highest in plausibility. The occurrence of an initial patch several days before the more widespread outbreak supports the parasitic origin; because it furnishes a focus whence infection may have scattered. Against the parasitic origin stands the absence of trustworthy evidence of contagion. Epidemics are undemonstrable. Where cases have appeared in close association, as in families or barracks, the circumstance of similar diet and similar hygiene detracts from the hypothesis of communicability. Yet this detraction is more inferential than real because the contagion may be feeble and selective. Just as it has been proven that the body louse will pick his host with instinctive discrimination, and that vegetable parasites do not thrive on every skin, so the parasitic cause of pityriasis rosea may need a soil of peculiar susceptibility. Analogous to the exanthemata in the occasional prodromal lassitude and adenitis, we are unable to adduce any further proof of the specific infectivity of pityriasis rosea. The semi-chronicity of its course, its response to external medication, the absence of demonstrable contagion, and the exclusion of children from the circle of its influence, rather tend to weaken the suggested resemblance. Here we are confronted with one of the oddest problems in dermatology. Etiologically it is a mystery. It evokes several hypotheses; none of which is adequately supported. It is sufficiently common to render its elucidation extremely desirable. While intrinsically unimportant it acquires factitious interest because of the confusion created by a paradiagnosis.

As in many another instance in dermatology, failure to recognize the condition depends largely on failure to recall its possibility. If it were added to the limited roster of cutaneous diseases in the hands of the general practitioner it would come up for differentiation in moments of perplexity, and would quickly establish its identity. Its salient features would be picked out and grouped and uncertainty would be quickly dispelled. The examiner would observe that "there are discrete patches, round or oval, tending to arrange themselves somewhat in the direction of the curve of the ribs. They are crinkly like cigarette paper and some of them display an epidermic cuff between the outer darker rim and the lighter centre. The outer rim is pink usually and the centre fawn. In more active cases the outer rim may be red and the centre salmon. But always there is the slightly scaly crinkly surface and often the epidermic cuff. The spots have been described as discrete. Sometimes they coalesce, but only to form combinations of segments of circles, each preserving its peculiar tinting and shading in the fragment that persists." When an examiner has that picture in his mind he will readily recognize it on the skin. Emphasis has been laid by reiteration upon the matter of the epidermic cuff. Borne in mind, that particular sign will bring assurance in the rarer manifestations where intensity of the efflorescence causes alteration in the bulk and contour of the units producing papular instead of macular lesions. The only title of pityriasis rosea to the consideration of practical men being its capacity for suggesting another diagnosis, the method of avoiding this naturally assumes the most commanding position in a treatise on the subject. That method would appear to be absurdly simple! Learn to recognize pityriasis rosea! Quite true. But the way to learn to recognize it is not only to note its own distinguishing features but the difference between them and similar but alien manifestations. Furthermore, while typical cases are easy to determine those which are modified by accidental circumstances sometimes assume aspects that are very confusing. Here it is needful to be acquainted with the diseases that may be stimulated. To distinguish A from Z it is requisite not only to know A but also to know Z, unless they are utterly unlike from all viewpoints.

Pityriasis rosea itches a little, sometimes. When it does it comes into collision with eczema. Those who are unfamiliar with the nicer differentiations of dermatology are so impressed with the versatility of eczema that they figure it capable of many diverse appearances. They are sure of one thing, however, and that is that eczema itches! This has the tenacity of a fixed idea! Like the fixed idea of the alienist it frequently leads to delusions. It comprehends within its scope every eruption with the same disturbance. But there are other characteristics of eczema which added to itching make up a different picture from that of pityriasis rosea. Eczema is infiltrated. Pityriasis rosea is not in the great majority of cases. Eczema occurs ordinarily in patches of no definite size or shape, shading off into the normal skin. Pityrisia rosea occurs in well defined round or oval patches with a clean cut demarcation from the normal skin. Eczema is vesicular and moist. Pityriasis rosea is dry. Eczema is scaly at times, but this is in the advanced stage of chronic lesions or in the terminal stage of acute. The scaliness, however, is heavy and coarse compared with the fine branny or filmy scaliness of pityriasis rosea. Eczema spreads peripherally, and without limitations. Pityriasis rosea produces patches of fixed proportions which do not increase in size. They may vary in size but do not change in individual instances.

There are exceptions to the freely spreading, vaguely bordered, manifestations of eczema. Circinate forms appear which we have been pusillanimously dubbing "parasitic" eczema! Either all eczema is parasitic (in the broad sense) and then this qualification is superfluous; or this particular variety is not eczema at all but ring-worm. But it can hardly be mistaken for pityriasis rosea despite its circular or oval outline, for it is apt to be in situations little favored by the latter (namely the hands and forearms), to be scanty in distribution; and to be thickened, oozing, pustular, or crusted. There may be only a patch or two; occasionally there are several, but they are never what we understand as numerous. Here we have brought out the diagnostic points of eczema. Comparison with the delicate tracery and coloring of pityriasis rosea will sharpen the contrast.

Dermatitis seborrhoica, sometimes known as seborrhoic eczema, is the paradiagnosis oftenest made by the dermatologist; when he is in doubt concerning a pityrisia rosea. Seborrhoic dermatitis is a patchy eruption, well defined, frequently dry, scaly, and but little infiltrated. It approaches closely the milder type of psoriasis. This will serve to fix its

description on the mind. Such an eruption will look a great deal like pityriasis rosea, if the latter happens to be a little exaggerated and the former happens to assume the ovoid type. Distinction is not always easy, but is always possible. The scales of seborrhoic dermatitis are greasy; even when they seem dry they reveal their real character upon friction between the fingers. They are heavier than the flimsy exfoliation of pityriasis. Even when the latter is more inflammatory than usual and denser in structure, the scales are apt to preserve their usual tenuity. If anywhere in the distribution of the eruption there is discovered a spot with the epidermic cuff heretofore described, the diagnosis can be stoutly maintained. The sites of election of the two dermatoses are liable to be the same. The chest and back with extension into the axilla and out upon the arm may be the stamping ground of both. This makes for confusion. We are assisted by the invasion of the scalp and face common in seberrhoic dermatitis and decidedly uncommon in pityriasis rosea.

But it must be remembered that seborrhoic dermatitis is one of the most familiar occurrences on the scalp. It is the cause of most of the baldness prior to old age. There seem to be few heads free from it. On some it is kept under control; on others it is not especially active; but on most it exists and on many it is devastating. It is likely that such a prevalent disease as this will be found in patients afflicted with other dermatoses. Pityriasis rosea then may easily be associated with it. Under these circumstances the differentiation may be troublesome. In fact the original diagnosis may have to be recast as we find after treatment that we are dealing with a dual affection. If we can get the definite signs of pityriasis rosea the duality will be evident, but if we are confronted with an atypical variety of it, the concurrence of seborrhoic dermatitis on the scalp may determine a paradiagnosis. That is no grave disadvantage, as the treatment for seborrhoic dermatitis would probably act favorably on the milder malady.

Multiple tinea circinata widely diffused might be mistaken for pityriasis rosea; conversely and more probably pityriasis rosea might be mistaken for multiple tinea circinata. Careful examination ought to prevent this error. Tinea circinata clears in the centre; pityriasis rosea shades toward the centre but does not actually clear; it retains its crinkly character, peculiar color, and filmy scaliness throughout. The edge of tinea is more prominent and it is obviously spreading peripherally; it is also vesicular or purulent or in a stage of evolution therefrom. An examination of the scales for fungus or spores will offer an eventual solution if the problem prove otherwise indecipherable.

Attention has been drawn to the possibility of mistaking pityriasis rosea for syphilis. It is this which gives reflected importance to an intrinsically insignificant cutaneous disorder. The resemblance must be rather close when keen observers are deceived. It is the maculopapular syphilide which it simulates. It does this only when its own lesions have lost their identification marks; when, instead of the non-infiltrated, slightly scaly, pink and fawn colored patches, it presents us with reddish papules, interspersed with reddish macules. In both lues and pityriasis thus intensified we shall find scaling. Presumptuous clinicians have asserted that the diagnosis is easy because pityriasis rosea does not attack the face and the syphilide almost always does. This is an excellent point. But the fact that the syphilide sometimes neglects the face detracts a little from its conclusiveness. The further fact that pityriasis rosea may be accompanied by a slight pharyngitis and adenopathy accentuates the doubt. To be sure, if we can get a history and find a chancre or its cicatrix, or if we can get the confirmatory concomitants of condylomata or mucous patches, or if the palms are invaded and the hair falling out, we are in an absolutely secure position. But it is in the circumstances where we lack these supports that we are apt to stumble and bring about a nasty contretemps! An example from life will be worth a page of admonition. A dermatologist confronted with an eruption that suggested lues questioned the patient (a girl of nineteen, unmarried) concerning her manner of life and under the trepidation excited by his apparent discovery of misconduct, induced her to confess that she had had sexual intercourse long enough before the cutaneous outbreak to establish an etiological association. Lues was promptly diagnosed upon this revelation and a Wassermann ordered. Meanwhile, just to give her something to do until the result of the serological examination should be known, a lotion of calamine and zinc was prescribed. One week later, coincident with a negative report from the laboratory, the eruption was observed to be fading. Had the patient kept her nerve and denied the soft impeachment she would have been triumphantly vindicated!

It is not at all likely that any other picture of syphilis will be found to counterfeit pityriasis rosea. If syphilis runs true to form there is little possibility of confusion. But we must always be alive to the occasions when it does not do so. If we are in doubt it will be much wiser to refrain from expressing it until we have tried the effect of local measures, for fear of exciting a syphiliphobia often far more intractable than the actual disease. A week or two will cause such a change in the eruption, as to dispel the indecision. Syphilis will not have been mentioned and no haunting suspicion of it will have been implanted in the patient's mind.

The treatment of pityriasis rosea is simple and speedily effective—as a rule. The calamine and zinc lotion is the first choice in the recent case. In two or three weeks the delicately tinted patches will be broken up into epidermal fuzziness more or less suggestive of a stubble field. This will gradually exfoliate, and leave the normal unpigmented skin. Sometimes stubborn cases will be met with in which we shall make little impression with our calamine lotion. Sulphur may be added to the lotion or a lotion of hyposulphite of soda may be used instead. Or the ointment of ammoniated mercury may be successful. The main consideration is not to irritate and set up a dermatitis on the site of the milder affliction. Cases have been known to persist for many weeks despite every effort to rout them. They may have been overtreated or they may have been obstinate from some unknown condition of their development. In any event there is no reason to lose confidence for they will ultimately disappear.

ACUTE OTITIS MEDIA PURULENTA AND ACUTE MASTOIDITIS AT THE BASE HOSPITAL, CAMP STUART, VA.*

By JOSEPH D. KELLY, M.D.,

NEW YORK,

FORMERLY CAPTAIN M. C., U. S. A.; VISITING OTOLARYNGOLOGIST, ST. JOHN'S HOSPITAL, LONG ISLAND CITY; ASSISTANT, MANHATTAN EYE AND EAR HOSPITAL.

THIS paper is not intended to be a reiteration of all that has been said on acute otitis media purulenta and acute mastoiditis, but is written with the hope that some of the conclusions reached and some of the observations made might be of value to the busy practitioner and of interest to some otologists. It covers a series of nearly two hundred cases of acute otitis media purulenta and some forty-eight cases of acute mastoiditis which came under the supervision and treatment of the writer while in charge of the Department of Otolaryngology at the Base Hospital, Camp Stuart, from and including the months of February to June, 1918. This includes the infections of the ear and mastoid which complicated the acute infectious diseases, especially the pneumonia (streptococcic) which became epidemic in the camps during the winter of 1917-1918.

Acute Otitis Media Purulenta.—Bacteriology: We endeavored to make a culture of the discharge from each acute infection of the ear, whether or not it complicated one of the acute infectious diseases. Chronic cases were not cultured.

Our method was as follows: The external canal was thoroughly cleansed with boric acid solution and cotton on an applicator, care being taken to remove all the caseous material. Then in like manner the canal was treated with hydrogen peroxide, fifty per cent. alcohol, and finally with a four per cent. solution of tincture of iodine. A piece of sterile cotton was then placed in the external canal and the patient was instructed to hold his head toward the affected side or ordered to lie down for a period of five to ten minutes before the culture was taken. Effort was made to get the culture as near the perforation as possible. Efforts to get through the perforation were usually unsuccessful because of pain and discomfort to the patient. Personally I do not believe that much would have been gained by getting it through the perforation, for the reasons explained later.

We used, in taking these cultures, a fine Yankauer Eustachian applicator fitted in the holder. This was used because it was the least flexible of any of the small calibered applicators at hand, and in addition carried a very small amount of cotton, and so enabled us to culture more easily from the part of the membrane at or near the perforation or incision and not from the walls of the canal or the whole membrane.

In taking cultures from the ears of patients suffering with acute infectious diseases, it was often impossible to follow this outline fully, either because of the poor condition of the patient, the difficulty experienced in trying to work with a bed patient who was unable to sit up, or other obstacles which the special men found at the beginning. So we satisfied ourselves with getting the canal as clean as possible under the circumstances. All cultures taken for study were made upon blood agar for the reason that we were thus able to detect the presence of any hemolytic organism on the first culture. I believe that blood agar should be used at all times when taking cultures from the ear or sinuses, in fact, in taking cultures from any infected area where the exact nature of the organism is not known.

As might be expected we found a great variety of organisms, such as reported by men who have made more extensive observations in this field. No attempt was made to discover anything new in the bacterial flora of the discharges, but we did endeavor to get pure cultures of some one organism, which might be identified as causing the existing infection. However, we soon abandoned this for the following reasons.

All acute infections of the middle ear come from the nasopharynx; of that we are satisfied. Except in very occasional cases, the bacteria must travel by way of the Eustachian tube from the nasopharynx where undoubtedly any number of pyogenic bacteria are present at all times. Hence the infecting organism must be forced up the Eustachian tube into the middle ear by the patient either coughing, blowing his nose, or otherwise creating a positive pressure in the nasopharynx. Is it logical to suppose that any one organism should be sorted out and forced up the tube to start the infection? We did not think so, but felt that it was more reasonable to suppose that the exciting organism was introduced together with other organisms from the nasopharynx and that under the favorable conditions following the inflammatory reaction caused by the inciting organism the other bacteria introduced with it would thrive and become active and give us mixed cultures in a very short time after the initial symptoms.

In the process of catheterization is it amiss to believe that we must introduce bacteria from the nasopharynx into the middle ear? Do not many men use the method for introducing argyrol into the middle ear in some cases of chronic catarrhal otitis media? If argyrol can be introduced in this way, why not secretion from the nasopharynx? Therefore, I am inclined to believe that there are pyogenic organisms of low virulence present in the middle ear at all times; that they do not cause infection may be due either to the immunity of the individual, or to some protective action exercised by the epithelium of the middle ear or Eustachian tube, other than ciliated epethelium. Hence it would follow that the organism or organisms producing acute purulent otitis media, must be introduced in sufficient numbers and be of sufficient virulence to overcome whatever protection nature provides against infections of the middle ear. However, it is reasonable to suppose that some organisms when alone introduced into the middle ear would not become active, but when introduced with other organisms would become active because of their symbiotic relations. This is what I believe happens when we have low grade infections of the middle ear, which we usually termed acute catarrhal otitis media, and would tend to explain acute purulent otitis media in the absence of any other acute infection. With great care, we were able to get some pure cultures.

*Read before the Brooklyn Medical Association April 1, 1919.

Streptococcus hemolyticus from our pneumonia cases, *Streptococcus viridans* from a case of scarlet fever, which later came to mastoiditis, *Staphylococcus pyogenes aureus*, the pneumococcus, and a hemolytic staphylococcus. These cultures were made very soon after incision or rupture, and we believe before the other organisms introduced with the inciting bacteria, became active, or reinfection from the throat had taken place.

After reaching these conclusions, we satisfied ourselves with ascertaining the number of virulent organisms present in any discharge, and those most likely to cause complications or mastoiditis, such as those of the streptococcus group, *Staphylococcus aureus*, pneumococcus, etc. The cultures taken during this period showed any variety of combinations of organisms, but the one most constant during the epidemic was the *Streptococcus hemolyticus*. We observed that those cases in which the culture showed the most virulent organisms, had the least discomfort, least pain, and the earliest rupture of the membrana tympani.

In the treatment of these cases, as you would expect, early and free incision was done under ethyl chloride anesthesia in thoses cases not ruptured or requiring better drainage. The patient was then instructed how to blow his nose, and what to do when he was compelled to cough or sneeze.

We used irrigations only on chronic cases, because I believe that the best you can expect from irrigation, performed as it is performed in the majority of hospitals today, is to help the reinfection already taking place from the nasopharynx, or wash out the caseous material adherent to the walls of the external canal. In the first place the initial infection occurs in the part of the atrium around the orifice of the Eustachian tube, the mucous membrane of the middle ear becomes swollen and edematous, thereby reducing the lateral dimension of the atrium. Your incision is made posterior to the handle of the malleus, your infection is anterior. When the irrigation is directed against the membrana tympani, that part of the membrane anterior to the incision and posterior to the handle of the malleus, being flaccid, either acts as a valve or is pushed against the swollen mucous membrane of the inner wall of the middle ear and prevents any irrigation of that part of the atrium first infected and possibly the only part infected at the time of the first irrigation. I believe that the best you can expect under these conditions is an irrigation or infection of the posterior part of the atrium or to have a new infection carried to the vault or possibly the antrum. I believe this will explain the fact that we sometimes find in cultures taken from the mastoid at the time of operation, an organism which was not present in the culture made from the discharge. I believe that in treating acute purulent otitis media in children, where the mastoid cells are few and large, irrigations should not be used unless we are positive our incision runs well anterior. For these reasons we used wicks entirely in treating this disease, keeping drainage established and the external canal free from any caseous material. Any case having a discharge, heavy and purulent, at the end of four weeks was considered to have some mastoid involvement.

Mastoiditis.—We were conservative in making a diagnosis of mastoiditis, sometimes I believe too much so; but we felt that it was better to err on the side of conservatism. Therefore, we made use of everything at our disposal and no patient was operated upon until we had exhausted every means to prove that he did have a mastoid requiring operations. In so doing we found that the *x*-ray had a place, but was not to be relied upon to clinch the diagnosis. Temperature means nothing at times, and cases having considerable mastoid involvement will sometimes show very elusive blood pictures. I believe, after all is said and done, the two things of importance in making a diagnosis of acute mastoiditis are the experience of the otologist and his ability to interpret the clinical symptoms and a summary of all laboratory findings.

We did not concern ourselves with the character of the organisms found in the discharge until the patient showed or began to show some symptoms of mastoid involvement, for we had observed cases whose culture gave the presence of such organisms as the *Streptococcus hemolyticus*, the *Streptococcus viridans*, and other virulent pyogenic organisms, run a slight elevation of temperature for 24 to 48 hours, and then clear up and be discharged within ten days or two weeks. Some of these patients had cellular mastoids, as shown by the *x*-ray, and were not sclerotic as you would expect.

Where it became necessary to operate upon cases the culture from which showed one or more of the streptococcus group present, especially the hemolyticus, we learned by observation that those cases which were operated upon within the first 24 or 48 hours after being admitted to the hospital had more reaction and were more liable to develop some involvement of the neck or sinus, than those which were operated upon a week or ten days after admission. Thus we began to consider these cases analogous to those cases of empyema which so often complicated pulmonary infections caused by the *Streptococcus hemolyticus*, and which when operated upon early usually had a fatal termination. However, in empyema it was found that where these cases were aspirated four or five times before operation they usually recovered. If these cases were benefitted by waiting a reasonable time for the patient to develop an immunity, we felt that we were justified in following a similar course in mastoid cases apparently caused by the same type of organism, and I am sure that it was for the best, as shown by their temperature charts and their recovery. However, in following this course we were fully conscious of the fact that we were diverting from the accepted surgical teachings concerning the treatment of acute mastoiditis.

I do not wish to go into details of the operation, but I would like to say that a thorough exenteration of all cells was performed in every case, and the sinus uncovered for examination. The only case developing sinus thrombosis was one in which the sinus was not uncovered for examination. All cases showing a streptococcus on culture from the mastoid were cases with marked destruction. There is little doubt with regard to the tissue-destroying properties of the streptococcus group.

It was necessary in a few cases to excise the tip either because of its necrotic appearance or of fracture.

We had seen the results of incomplete operations and we were able to compare these with the complete

exenterations, and we found that the latter repaired more rapidly with no scarcity of granulations. We used in dressing our mastoid cases solutions of dichloramine-T in strengths of 2, 5, or 10 per cent., and I believe that the average number of days the patients were kept in the hospital was well within the recognized limit.

We had three deaths in this series, and I have made a brief report of each case.

Prt. X. Convalescing from streptococcic pneumonia. I was asked to see this patient on about the twelfth day of his illness. Patient's temperature was varying between 99° and 101°. He gave a history of having some pain in the right ear and discharge for the previous day. Membrane was incised for better drainage. Culture taken showed *Streptococcus hemolyticus* and staphlococcus present. Two days after the patient developed definite mastoid symptoms. With the consent of the Medical Service, chloroform anesthesia was administered and the operation was performed; time, about thirty-five minutes. Patient returned to the Ear Service. He did very well until after the first dressing on the fifth day. At this time the other ear began to discharge. About the seventh day he developed violent infection of the cervical glands on the right side. The glands were incised and drained about four days after infection first appeared. Next day he showed signs of recurrent pneumonia, and about a week later empyema on the right side. Patient died after being under our care about three weeks.

The interesting feature about this case was that we were able to obtain the *Streptococcus hemolyticus* in almost pure culture, from the sputum, both aural discharges, mastoid, glands, and pleural cavity. The blood culture was not positive until late in this case. This is a very virulent organism and demands consideration and study wherever found.

Prt. Y. Admitted to the hospital with acute purulent otitis media on the left side. The ear had been discharging for two days before admission. There was definite mastoid tenderness, the man complained of pain, the culture showed *Streptococcus hemolyticus* present in the discharge. Operated upon second day after admission. Considerable destruction, complete operation, but sinus not exposed for examination because we did not think it necessary at the time. Patient returned to ward. Next day he was able to go to the lavatory. On the fourth day he developed chill; temperature 105.5° about five o'clock P.M. Blood culture was taken. Next morning patient taken to operating room without waiting for report on blood culture. Examination showed sinus to be thrombosed. Jugular resection done, sinus opened, and clot about 3 inches long removed. Patient did exceptionally well for seven days. Temperature came down to between 99.5° and 101° next twenty-four hours, and remained under 100° thereafter. Patient insisted upon getting out of bed and occasionally walked about the ward, and would not listen to instructions relative to keeping quiet. On the eighth day after operation I saw this patient, about 4.30 P.M., sitting up in bed eating his supper. He seemed very well and I was gratified with the result. About six o'clock the same evening I was hurriedly summoned to the ward to see the man, who was in an uncontrollable state of excitement, with amnesic and ataxic aphasia, apparently not understanding what was said to him and unable to answer. It became necessary to restrain him in bed. Morphine had no effect. His pulse at this time was about 140; no dyspnea. The wound was explored and sinus found free, nothing to indicate further procedure. Patient died at 3 A.M. following morning. I am sorry to say that we did not get an autopsy of this case, nor did we get a spinal puncture. However, our diagnosis was a probable thrombosis or embolus affecting the bulb.

Prt. Z. Admitted to the hospital (G. U.) for observation because of pus in urine and systic irritation. He was admitted about eight o'clock in the morning, and because of his discharging ear was referred to the Ear clinic about eleven o'clock. There was a history of having a discharge for some time, he did not know just how long, perhaps six or seven weeks. But it did not bother him so much. Seemed to be more worried about his genito-urinary condition.

Examination showed a heavy-set, robust-looking man about twenty-seven years old, apparently in good health except for the large swelling which he had at the base of his right mastoid. Temperature about 102.5°. There was a marked Bezold abscess. He was sent to his ward with instructions to have him transferred to the Ear Service for operation at 1.30 P.M. Through his absence from the G. U. ward and his sudden transfer to our department, preparation for operation, etc., we overlooked the routine examination of his urine. The mastoid was opened and a large amount of pus was found, showing *Staphlococcus aureus*, which probably outgrew the organisms causing the original destruction. Patient took the anesthetic badly, went into a stage of collapse, and died before we could remove him from the table. Autopsy showed a double pyelonephritis, endocarditis, enlarged thymus, and extradural abscess. I believe this case tends to substantiate some of the literature written on the metastasis from the mastoid causing lesions of the heart and kidneys.

Conclusions.—1. It is very difficult to obtain a pure culture or to know the inciting organisms in acute purulent otitis media.

2. Mixed cultures will invariably be present after 24 hours of discharge.

3. The presence in a discharge of virulent pyogenic organisms does not necessarily mean that mastoid involvement will follow.

4. The individual anatomical characteristics of the mastoid may not be a deciding factor in the development of mastoiditis.

5. Acute purulent otitis media should never be syringed with the hope of irrigating the middle ear. Free drainage with or without wicks is the treatment to follow, keeping the canal free from obstruction. A piece of absorbent cotton may be placed in the auricle to absorb the secretion and this covered with a handkerchief or bandage.

6. The *x*-ray in acute mastoiditis is not to be depended upon for diagnosis.

7. An acute purulent otitis media lasting over three weeks and discharging freely at that time invariably means mastoid involvement and should receive operative treatment in order to preserve hearing and protect against the condition becoming chronic.

8. A complete exenteration of all possibly affected cells should be done at the time of the operation.

40 East Forty-first Street.

EPIDEMIC ENCEPHALITIS WITH GENERAL PNEUMOCOCCUS INFECTION WITHOUT PULMONARY INVOLVEMENT.

By CHARLES E. O'CONNOR, A.M., M.D.,

WASHINGTON, D. C.

On Sunday afternoon, April 6, 1919, Chester D. æt. 5, was at play outdoors and suddenly began crying and, running to his mother, complained bitterly of hurting in his head. He was put to bed, was extremely irritable, had an "awful high fever," and cried all night and the following day without complaint of pain in any specific place.

When seen for the first time, in the late evening of April 7, the child was most irritable, screaming and crying at the slightest thing and even without apparent cause. He had never before been sick

since birth and was regarded as particularly healthy, with the exception that he had suffered some discomfort from adenoids. The familial history was negative.

When spoken to he would answer quietly and rationally, but the screaming and crying would recommence immediately, continuing for a short period, ceasing abruptly with apparent lapse of consciousness, with upward rolling of both eyes lasting half a minute, to again begin the cycle. The axillary temperature was 104.2°F. pulse 124, respirations 24; the thoracic and abdominal viscera were normal, the mucous membranes of the entire buccal cavity were very much inflamed and both tonsils greatly swollen. No other departures from the normal could be discovered, but during the night the right membrana tympani ruptured, permitting the escape of a foul discharge.

On the morning of April 8, his condition remained unchanged. In the evening, in consultation with Dr. James M. Moser, it was discovered, in addition, that the spleen was somewhat enlarged. The degree of enlargement and its further development could not be determined on account of a gradually increasing rigidity of the abdominal walls. The various signs and reflexes could not be determined because of the patient's restlessness and irritability. Dr. Moser was unwilling to accept the tentative diagnosis of encephalitis in the irritative form.

It was reported on the morning of April 9 that the child had not slept at all, crying incessantly and complaining of a pain in his "stomach". The temperature per rectum was 97°F. respirations 30, pulse 130. In the evening the temperature rose to 104° per axilla, there was ptosis of the right upper lid, with paralysis of the right side of the face, and inability to completely close the right eye; the left leg was tightly flexed upon the thigh and the thigh upon the abdomen. The patient lay on his right side and said he could not lie on the other side or on his back, because it hurt him. However, there was no paralysis of this limb; it could be moved, but only under protest and any manipulation or pressure on it evoked piercing shrieks.

In the afternoon Dr. C. R. Dufour, consulting otologist, made an examination of both ears, found that the perforation of the right membrane was sufficiently large to permit free escape of the discharge and that neither mastoid was affected.

The next morning, April 10, it was learned that the child had again failed to sleep, was very restless and irritable, crying and complaining of his stomach. No local tenderness was shown, nor could the child fix the site of the pain. The temperature was then 99°, but later in the morning another chill developed to give place to an evening temperature of 104° in the axilla.

In the evening another consultation was held, this time with Dr. Thomas N. Vincent, who concurred in the diagnosis of epidemic encephalitis, but to establish the diagnosis without question, the opinion of other diagnosticians was sought.

On the following day, Capt. J. E. Dwyer, M. C., U. S. A., chief pathologist of the Army Medical School, conducted an exhaustive examination and arrived at the conclusion that the diagnosis was unquestionable. Cultures were secured from the discharge from the right ear and from the secretions of the nose and throat, from which were grown colonies of an unidentified hemolyzing staphylococcus. The discharge from the right ear ceased after the seventh day and gave no further trouble.

From the onset of his illness until April 11, the child refused all nourishment and could not be prevailed upon to sip even a little water, but on this date he was forced to take a little iced milk, and as the swelling of the tonsils and the inflammation of the mouth began to subside, his demands for water became incessant at all hours of the day and night. The cerebral excitation present from the beginning still persisted and despite the free administration of narcotics and sedatives, it resisted subjection and the child had obtained but little sleep. However, after the end of the second week, the sleeplessness was gradually overcome, the periods of sleep growing longer and longer, with the peculiarity that they occurred during the day, while the sleeplessness occurred at night.

On April 12 the father was compelled to go to bed, suffering from great weakness, headache, and pain in back. His temperature was 103°, the tonsils were greatly swollen, and the mouth and throat were very red and sore. After the third day he was able to get up and allow his wife to go to bed with precisely the same symptoms. She was also confined to bed for three days. A little cousin, with whom the patient had been playing on the afternoon of April 7, was taken ill on April 8 with "tonsillitis," which lasted four or five days.

The general condition of the patient remained about the same, temperature 103° (in axilla), respiration 24, pulse 124, until the close of the seventh week of illness. No chill occurred after April 10. At the end of the second week, the irritability and restlessness began to abate and appetite and assimilation became more and more satisfactory. A very generous diet was permitted and the stools disclosed no undigested particles.

During the night of April 23, a soft swelling about two inches in diameter appeared under the skin over the sacrum. Fluctuation and tenderness over the site of the swelling were absent, but pressure on or manipulation of the left thigh evoked vehement protest. In another consultation with Dr. Vincent noninterference was decided upon. The swelling remained stationary in size and appearance until the seventh week, when subsidence began with complete disappearance at the end of the eighth week.

During the night of April 30, two other swellings suddenly appeared, one deeply situated in the left vastus internus, the other between the skin and the left infraspinatus and teres major in the vicinity of which there was no tenderness, nor could fluctuation be detected. There was no enlargement of any superficial glands anywhere. The abdomen on this date was greatly swollen, with protrusions of the navel, but without pain, signs of effusion, or actual tympanites. The condition of the left thigh and of the abdomen remained stationary until May 30, when rapid improvement commenced.

Puncture of the swelling of the left shoulder was not considered advisable by either Dr. Vincent or Captain Dwyer. However, it gradually increased in size and finally ruptured at the posterior border of

the axilla on May 26, giving exit to fully a pint of greenish, creamy pus, the bacteriological examination disclosing a few streptococci and an enormous number of pneumococci of group IV. The patient's condition began immediately to improve; the discharge from the abscess had ceased by the seventh day and the break in the skin had completely healed, and while convalescence was not completely established, it was considered safe to permit him to go to the home of his grandmother in Georgia, on June 4. It is to be regretted that urinary and blood examinations were not secured.

On June 4, the day on which patient was last seen, there was still flaccidity of the right side of the face and inability completely to extend the left thigh.

The patient again came under my observation July 10, 1919. He was very bright and active, had gained considerably in weight, and the paralysis of right side of face only faintly noticeable. All signs of localizations of pus had disappeared save a very slight discharge from the right ear. However, the inability to use the left leg persisted. It was slightly flexed but could be voluntarily and freely moved in all directions without pain, all muscles of the limb were atrophied, the greater trochanter was felt an inch and a half upward and backward from Nelaton's line and there was two inches shortening of the thigh, the röntgenogram disclosing absorption of the neck of femur. All active inflammation had ceased.

THE WHISPERED VOICE SOUND, AN AID TO THE EARLY DIAGNOSIS OF PNEUMONIC CONSOLIDATION.

By HENRY H. LISSNER, M. D.

Los Angeles, Calif.

Medical literature has been overwhelmed with reports, statistical, clinical, and laboratory, about the recent epidemic of influenza and pneumonia, and probably no phase of the disease has been omitted in the course of these studies. Early in the epidemic, it was evident that those patients who developed pneumonia, were in less danger of serious consequences, if unnecessary handling and physical examinations could be avoided.

How best to diagnose early pneumonic consolidation before the ordinary physical signs of pneumonia were in evidence, was the problem.

Ordinary Methods of Diagnosis Were Misleading.—The diagnosis of pneumonia as generally understood and based upon palpation, auscultation, and percussion, was to a very large extent unsatisfactory, as we were dealing with an acute respiratory infection which gave objectively, hemorrhagic sputum, temperature, cough, cyanosis, and dyspnoea. On auscultation, there were numerous rales of all descriptions, or in many cases no rales at all. The breath sounds were exaggerated and if one tried to elicit bronchial breathing by having the patient take an extra amount of air into the lungs, the effort was usually followed by a violent fit of coughing which lasted some three to five minutes, increased the pulse and the respiratory rate, and produced such apparent exhaustion in the patient that further examination had to be postponed until the patient recovered.

On percussion in the early influenza cases there was very little change except probably an impaired resonance which was distributed generally over the entire lung area. Small areas of patchy consolidation were not easily made out under this circumstance and until they were of sufficient size to be demonstrated by percussion, the usual other physical signs of pneumonia were present.

Is there a physical sign which would be sufficiently accurate from the diagnostic standpoint for the determination of early consolidation independent of the well-known signs of pneumonia?

Transmission of the Whispered Voice.—After having examined several hundred cases of frank pneumonia at the base hospital, Camp Pike, Arkansas, it was noticed that bronchophony was a constant accompaniment of every case and it was felt that this physical sign was merely an expression of transmission of sound through the bronchi to the chest wall, due to increased lung infiltration.

These sounds coming to the ear in exaggerated form, led to the thought that the whispered voice sound would be as evident, and it was found that small areas of patchy consolidation which were not demonstrable by percussion and over which bronchial breathing was not determinable, were brought out and could be sharply defined by this method. Carrying this idea further, it was found that the entire lung surfaces could be examined systematically in a short space of time with the ordinary bell of a Bowles' stethoscope, by going from ring to ring as marked on the chest wall and by this method, the areas of consolidation could be sharply outlined and nicely differentiated from the uninvolved area immediately adjoining it.

The point or place of the whispered voice sound is not new in physical diagnosis, but its application to the diagnosis of early pneumonic consolidation, is a new departure and gives to this particular sign an added value.

Occurrence in the Normal.—Numerous normal individuals were examined and it was found that the whispered voice sound is transmitted over the same areas where we find normal increase of breath sounds: namely, near the hylus of the lung, between the shoulder blades, and under the upper end of the sternum. There seems to be a tendency also for the voice transmission along the spine of the scapula, but here the sound is not so clear-cut and fades toward the periphery. If the stethoscope bell is placed over the external occipital protuberance and the individual whispers, "One, two, three," the bony skull will conduct the sound of the voice, and give a clear, audible, and distinct repetition of the sound such as heard in pneumonia.

The Effect Upon the Patient.—The effect upon the patient of this method of examination which, to a very large extent, eliminated a great deal of handling, was quite noticeable. It was unnecessary to have the patient take an exaggerated breath, because after whispering, "One, two, three," he voluntarily took a breath of sufficient depth to reinflate his lungs, during which time the character of the breath sounds could be made out. It also prevented the serious coughing attack and the increase in the respiratory rate, from exertion.

Conclusions.—1. Auscultation is more important than percussion for the early recognition of pneumonic consolidation.

2. It is possible by this sign to diagnose pneumonia even in the absence of bronchial breathing and dullness.

3. The type of pneumonia may be determined by the extent of the whispered voice transmission and the line of demarcation between bronchopneumonia and lobar pneumonia is easily made. However, in those cases of confluent bronchopneumonia, it is not satisfactory.

4. The physical sign of the whispered voice sound is an aid to early diagnosis of pneumonia and is valuable because it makes for the early isolation of the patient in hospital wards.

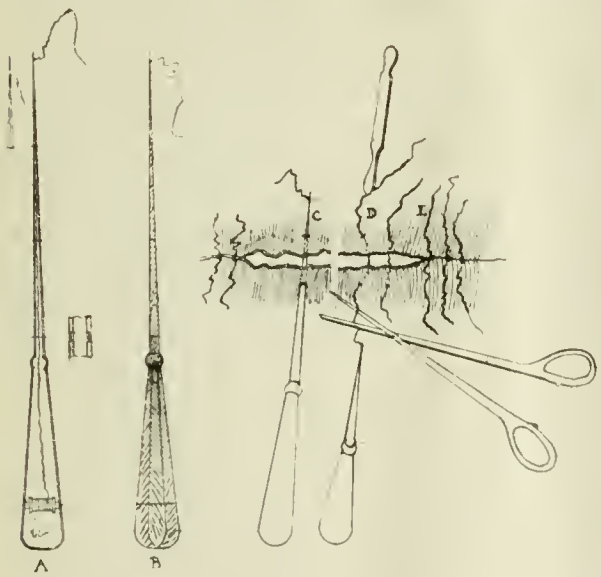
A NEEDLE CARRYING A CONTINUOUS SUTURE.

By ALFRED KAHN, M.D.,

NEW YORK.

The idea of the instrument herewith illustrated is intended to overcome the threading and rethreading of needles, where sutures are to be placed in deep or narrow cavities like the throat or nose. In a larger sense, it can be used for stitching surface wounds.

The needle is made up of several parts which can be screwed into each other, and a spool for holding the thread. The instrument is made up in these



several parts so that when they are screwed together, the thread passes down from the spool through the center of the instrument throughout its full length, leaving the instrument at a minute opening (needle hole) near its tip, and is then pulled through sufficiently long for a ligature.

Technique.—The parts of the instrument having been joined together, both sides of wound are pierced and the ligature pulled through. The instrument then retraces itself and the ligature is cut away from the instrument and is tied. When the ligature is cut away, there is enough of the thread left extending from the instrument through its needle hole to allow the next ligature to be unwound from the spool, and the next ligature is ready. This process is repeated until the wound is entirely united.

In the illustration A illustrates longitudinal section, and B shows the same instrument in elevation. C, D, and E illustrate the technique of the procedure.

ABSENCE OF THE PROSTATE.

By J. HENRY DOWD, M.D.,

BUFFALO, N. Y.

The following case report is of interest from several standpoints. First, its extreme rarity. In the examination of many thousands of prostates during the past 30 years, I have never before met with its entire absence, or with one so small that detection was impossible with the finger.

Second: A N. Y. Supreme Court Justice has within the past month annulled a marriage on account of impotence on the part of the male; medical expert testimony was given, "it was due to the absence of the prostate gland".

Third: The prostate gland is in no way concerned in erection in the male. Men of reasonable age who have had their prostate removed have had no trouble in producing erection; rarely are they impotent. The function of the prostate is well known; its secretion dilutes the seminal fluid, thus facilitating its easy passage through the urethra, and it gives motion to the spermatozoa, for they are motionless in its absence.

J. S., aged 32, sent me in consultation as being possibly the sterile factor in the partner in the marriage, he having been married six years. Father died of tuberculosis when he was a child; J. S. showed no evidence of the disease; in fact, he was in apparent health, except a tachycardia which was accompanied by a mitral murmur, about every tenth or twelfth beat. (He had been rejected by the army surgeons for this reason.) Examination of the urine showed no evidence of inflammatory action, of diabetes, or of disease of any part of the urinary track. He acknowledged he was of a very nervous temperament which might account for the tachycardia; he did not smoke; phosphatic index was 65 per cent. below normal; using phosphatometer.

An examination of the prostatic region for pus showed an entire absence of the gland; there was no pus present nor prostatic fluid. It is my practice in all cases of sterility to have a drop of seminal fluid caught in a small bottle and brought for examination within a few hours after it is passed; if it is kept moderately warm and viewed within 24 hours, the spermatozoa may be found in active motion.

In this case I made the examination of a reasonably warm specimen only a few hours after being passed. Only an occasional spermatozoan was seen, and all were motionless, small, and apparently deformed.

He acknowledged he had possibly overdone the act of coitus, having at no time any trouble in producing erection, and whether the atrophy, if such it was, was due to this cause or to the gland being tuberculous before puberty, undergoing spontaneous recovery with atrophy, it is impossible to say. At least one thing was proven: erections were normal, and owing to the absence of prostatic fluid, what few spermatozoa were present were without life.

9 North Pearl Street.

Isoserotherapy in Tuberculous Meningitis.—Sahrazes and Piéchaud state that in a patient, aged sixteen, with this malady lumbar puncture was performed and the blood serum of the mother injected to replace it. This injection was also repeated and in each instance improvement was in evidence. While the patient was lost, the authors will continue their work, beginning at an earlier period in the disease and increasing the intensity, perhaps making further injections as in the veins, etc.—*Gazette hebdomadaire des sciences médicales.*

Medical and Surgical Lessons of the War.

TRENCH FEVER.

By R. D. RUDOLF, C.B.E., M.D. (Edin.), F.R.C.P.

TORONTO, CANADA.

PROFESSOR OF THERAPEUTICS, UNIVERSITY OF TORONTO; COLONEL, C.A.M.C.; CONSULTING PHYSICIAN TO THE CANADIAN FORCES IN ENGLAND.

Trench Fever has been one of the commonest causes of disability in all the Forces engaged in the recent great war. It has been stated that no other infection has caused so much sickness among the troops as it has. While not a fatal disease, it is often a prolonged sickness, and thus, besides being such a fruitful source of loss of man power, it also causes much suffering and keeps many men below par, although they are still able to carry on in a low category.

According to McNee, 90 per cent of all the sickness in one of the British armies was at one time due to this infection. But the chief importance of discussing the disease at this late stage is that it will probably be the source of much chronic ill-health amongst discharged soldiers, and also because the disease will probably be more or less common among the civil population who come in contact with such soldiers.

The name "Trench Fever" has been widely accepted as a proper one for the disease, because of the close association of this with trench warfare. There has been a too great tendency in medical writings lately to affix the term "trench" to all manner of diseases, but, in the condition under discussion, it is justifiable, for although we certainly know that the infection is transmitted almost always by the body louse, still the association of trench life with lousiness is so close that the term "trench" may be correctly used in describing the disease. Many other names, however, have been applied to the condition:—at least, to conditions that in all probability are the same. Some of these are the following:—Volhynian Fever, Quintan Fever, Polish Fever, Ikwa Fever, Russian Intermittent Fever, Meuse Fever, His-Werner Fever, Gaiter-pain Fever, Shin Fever, Trench Shin, and Shank Fever. Many of these names suggest the wide distribution of the disease, and it has indeed been reported from every front.

The first case of trench fever was described by J. H. P. Graham[1] in the Summer of 1915. A. Migo[2] states that it commenced amongst the French in the following year, principally in the Champagne sector. It was first described on the German side by His in 1916, and was termed by him Volhynian Fever, but he states, that it was not confined to that district. P. Sisto[3] was the first to record its appearance amongst the Italian troops. He states that little was known of its etiology, except that human beings can be directly infected by means of the blood of patients, and indirectly by lice.

But it is not at all probable that the disease is a new one. Every physician on looking back over his hospital experience will be able to recall many cases of indefinite fever, which were then, after all the known causes of fever had been excluded, often classified under the delightfully indefinite diagnosis of Febricula. Many of these would now be called trench fever, and probably in some cases correctly, although possibly the pendulum will for a time swing in the other direction and the tendency will be to diagnose too many as trench fever. Moreover, already, since the description of trench fever has appeared in the journals, a number of instances of its occurrence amongst civilians have been recorded.

The probabilities are that the great lousiness of a large group of men, often closely crowded together, caused an epidemic of an infection which had existed before in an endemic form. There is some historical evidence, also, that such epidemics have occurred in former wars. Thus, Saint Simon, in his Mémoires, calls attention to the prevalence of low types of fever among the troops in Flanders during some of the campaigns of Louis XIV, and many of the fevers described during the middle ages may easily have been of this nature.

Essential Nature.—At first it was thought that trench fever was paratyphoid or typhoid fever, modified by inoculation. Hunt and Rankin[4] examined the feces, urine, and blood of many typical cases of the disease for typhoid bacilli, but failed to find them, and hence concluded that they were not dealing with any of the typhoid group. The British Investigation Committee on Trench Fever, in their second Report[6] pointed out that in cases of fever occurring amongst inoculated men, and which from clinical signs and agglutination tests belong to the typhoid group, some 40 per cent show typhoid bacilli in the blood or excreta during some period of the illness and yet they found these absent in over 200 cases of trench fever, and, further, these all gave negative agglutination tests for typhoid and paratyphoid. McNee, Brunt and Renshaw[9] and many other workers were similarly unable to obtain typhoid or paratyphoid bacilli from such cases, and hence they also concluded that the disease did not belong to this family of infections.

Apart, therefore, from actual inoculation work, it seemed quite proved that trench fever is in no way related to the typhoid group, although, clinically, many cases may long remain in doubt.

Much work has been done in regard to the nature of the infection in trench fever, but the matter is still not cleared up. Various organisms have from time to time been discovered in the blood and urine. Thus Dimond[7] described a Hæmogregarine, but this work was not confirmed. Spirochetes have often been noted as occurring in the blood and urine. Remer, in 1917, found them in direct blood films from cases of Volhynian fever, which is undoubtedly the same disease. Later, in 1917, Nankivill and Sundell recorded spirochetes in the urine of such cases. In a discussion in May of last year on trench fever, Bassett Smith[8] said that French workers had inoculated guinea pigs with blood taken from trench fever cases during the pyrexial period, and that spirochetes subsequently were found in the heart blood of the animals. The immunising reaction of these was not the same as that of icterohemorrhagic fever. A. C. Coles[9] has recently demonstrated spirochetes in the blood of cases of trench fever experimentally produced at the Hampstead Hospital. They stain a pale blue colour with Giemsa, which is unusual in spiro-

chetes. Thus spirochetes cannot be said to have been ruled out as occurring in trench fever, and they may yet be shown to be an occasional phase in the life cycle of the virus.

Jungmann and Küczyuski[10] described a dumbbell organism (consisting of 2 granules connected by an intermedial portion, so that it was not a bipolar bacillus or a diplococcus) one or two m.m. long and staining with Giemsa, as a responsible cause. This organism was present in the blood with great constancy during the initial fever, and during the paroxysms. Attempts at cultivation failed. Exactly the same organism was found in typhus and in no other disease. Some, indeed, have suggested a resemblance between trench fever and modified typhus (Brill's disease). Lice were found to have these bacilli in the contents of the alimentary tract a few hours after being fed on trench fever patients.

The careful workers of the American Red Cross Commission on Trench Fever failed to find spirochetes or any other organisms constantly in the blood of cases of trench fever, and when mice, white rats, and guinea pigs were inoculated subcutaneously and intraperitòneally with the blood of these patients, no organisms were subsequently found in the blood of the animals. Quite recently Rose Bradford, Bashford and Wilson[11] have demonstrated the occurrence of an ultramicroscopic filter-passing organism in the blood of such cases, as in that of nephritis, measles, and many other diseases. So the matter is not yet settled, although, as will be shown, this fits in well with the American Commission's finding, where the infectivity of a filtered blood serum was proved. The Wassermann reaction is negative in trench fever.

Transmission of the Disease.—McNee[12] found in 1916 that if the blood of an individual suffering from trench fever be injected into the vein of a volunteer, the latter develops the fever in a few days. He further found that, while injection of the whole blood or of washed blood cells gave positive results, blood serum or blood plasma or filtered crushed blood cells could be injected without causing the disease. He hence concluded that this was due to an organism which was closely connected with the blood cells, and which would not pass through a filter. Subsequent work has modified several of these points. The filtering of blood plasma is a difficult thing, but the American Commission found that if suspensions in saline solution of the urine or saliva of trench fever cases be filtered through an unglazed porcelain filter (Chamberland, L.), the filtrate, when injected into the blood of volunteers, often produces the disease. The Commission concluded that the virus of trench fever is filterable in at least one stage of its existence, resembling in this respect, the viruses of typhus, phlebotomus, and dengue fevers.

When in 1915 trench fever became epidemic among our troops, much speculation arose about its natural manner of transmission. McNee, Brunt, and Renshaw[6] first thought, "that the disease is contagious from man to man, or, what seems much more likely, is carried by one of the common flies or parasites found in the trenches." Sir Wilmott Herringham[13] wrote in 1916 that "The two sources of infection which have been in the minds of all Officers of the Medical Services are lice or some kind of fly or mosquito. There are difficulties in both hypotheses. It has been sometimes stated that the continuance of the disease during the winter months is conclusive against flies or mosquitos. I do not think this is true, for I have seen mosquitos throughout the winter. But it is impossible to explain how one division, lying between two others which were badly affected, in ground quite as full of mosquitos as theirs, should escape so much more lightly if these insects conveyed the disease. The statements of patients are valueless; most men do not notice bites, and all were bitten by so many insects that they could not tell one from another. On the other hand, many Officers and Sisters working in Clearing Stations had the fever. None of them can have had more than an accidental louse bite, and some of them have declared that they have never been bitten by lice at all. The D. A. D. M. S. of Division C, told me that in the summer, when the fever appeared, the men were not nearly so lousy as during the winter, and indeed, were little troubled by lice. But it is noteworthy that Division B, which had but few cases, had much better facilities for baths than either of the other two, and that in Division A, the incidence is, on the whole, though with striking exceptions, greater on the dirty battalions than on those that were clean".

Rats and mice were blamed by some. Thus Rutherford[14] wrote that it seems reasonable to suggest that the field vole, or field mouse may perhaps be the source of the infection, and he pointed out that the field voles examined were found to be infected with ticks. Dimond, who described a Hæmogregarine as the cause of trench fever, thought that this might be transmitted "by a louse allied to the *Hæmatopinus stephensi*, described by Newsted and Christopher[15] as parasitic in the Indian field, and *The Lancet*, in an editorial, said, "If further investigation confirms the suggestion that the protozoon of trench fever is a hæmogregarine, it becomes highly probable that either the *Pediculus corporis* or a louse allied to the one parasitic on the Indian field rat is the carrier of the protozoon. The association of this fever with trench life, where large numbers of rats come in close association with the troops, favours this conclusion."

Since then the body louse has been more and more incriminated and finally has been shown by many experimentors to be at least the common intermediate source of the disease. Davies and Weldon[16] were apparently the first actually to prove this by experiment. In their own words, "Some scores of lice were collected and starved in captivity for one day. A number of them died. Two pairs of the survivors were taken and allowed to bite, under a watch glass, two patients suffering from trench fever in the acute stage. After allowing them to feed for about fifteen minutes their meal was interrupted, and each of us then allowed a pair to feed upon himself, strictly confining their sphere of operation by means of a securely-fixed watch glass. The one of us whose duties did not bring him into the Wards subsequently, 24 hours later, allowed a pair to have a further meal upon him. Twelve days later very interesting developments took place. The characteristic symptoms mani-

fested themselves, and he passed through a most typical attack of the condition of the average sufferer, with the pains and other features present. It may be further added that the victim had not at any time been nearer to the Front than the Base, nor had he been subject to any previous similar condition". They do not mention whether the other experimenter became infected. Much criticism was made of this experiment, but subsequent work has shown that it demonstrated the truth.

The very thorough and conclusive work of the American Trench Fever Commission, first published on March 9, 1918, completely convicted the body louse as being the carrier of the disease, and brought forth many details as regards the infection. They showed (1) that fresh lice, who have not previously fed on anyone, do not cause the disease in those whom they bite. (2) That the bite of an infected louse will transmit the infection without any scratching. (3) They showed that lice which have fed on trench fever patients can transmit the disease to volunteers many days after the lice have been removed from the source of infection, and that they can infect one individual after another for days. This shows that the disease is not in these cases due to direct transference of infected blood from a patient to a healthy person. Thus, some lice were fed upon a case of trench fever for some days. Thirteen days later they infected a healthy volunteer. During the thirteen days they spent three days on one subject and infected him: then a second subject and infected him: then a third and affected him: then a fourth and infected him, thirteen days after they had been removed from the original case of trench fever. (4) Contrary to what Davies and Weldon found, they obtained no evidence that lice can infect a healthy subject within six or seven days after being taken from the body of an infected person, which would tend to show, as was also done by the Hampstead Commission, that either the virus must have time to multiply in the body of the louse, or else that it undergoes an intermediate life cycle in the insect. But from the fact that direct inoculation of the blood of an infected person into a healthy volunteer will produce the disease, and also similarly that the virus from the urine or the sputum will give the infection when rubbed into an abraded surface of the body, it is evident that this intermediate life cycle in the body of the louse is not a necessary stage in the life history of the virus. The same thing is seen in malaria, the virus of which usually passes through an intermediate stage in the mosquito, and yet if the blood of a malarial patient be directly injected into another individual the disease may occur.

The Hampstead Trench Fever Commission published their first report on March 25, 1918. They came to the conclusion that the bite of an infected louse would not transmit the disease, but that this was passed on through the feces or the crushed bodies of such lice being rubbed ito abraded surfaces of the skin. Many workers have since found that the disease can undoubtedly be thus transmitted, but the weight of evidence is in favour of the bite of the insect also being able to cause the infection. They found that the feces of healthy lice would not produce the disease.

Incubation Period.—Infection with lice is such a constant feature of trench life that it was impossible from clinical observation alone to arrive at any estimation of the length of the incubation period of the disease. But by experimental infection various workers have shown that this period is very variable. The onset seems to occur at from 10 to 38 days or even longer after men have been bitten by infected lice, and from 5 to 20 days when the condition is brought about by the inoculation of infected blood or after it has been caused by the introduction of the virus through an abraded surface of the body.

Variations in the length of the incubation period probably depend upon the virulence and number of the organisms in the introduced virus and probably also upon the degree of natural immunity that happens to exist in the individual thus infected. Very few persons seem to be naturally immune to the disease, although they take it with very different degrees of severity, which points to a varying amount of resistance to the infection. The Hampstead Commission found that after infection with lice excreta through a skin abrasion, the incubation period was very constantly eight days.

During the incubation period the patient may not feel very well, being subject to headache and pains in various parts of the body, but usually the onset occurs quite suddenly, with no preceding symptoms.

Types of Trench Fever.—Trench fever presents such a variety of types that it is difficult to sketch them all clearly. No doubt many different diseases have from time to time been included under this diagnosis, the name having lately largely replaced the military diagnosis of "P. U. O.", but, even when all possible other diagnoses are excluded, a number of different types remain, which are examples of the same infection. Finally, it has been shown by inoculation experiments that when the blood from a single case of the disease is injected into a number of volunteers, these individuals will show very different forms of the disease.

McNee originally described two types of the disease: (*a*) a short one, and (*b*) a long one. The short type was characterized by a remittent fever, lasting some 7 to 12 days, and often followed by a single short relapse. (See charts 1 and 3). The long type showed a short initial bout of fever, followed by an indefinite number of brief relapses, occurring at intervals of from four to eight days. (See chart 2).

But it was soon found that many undoubted cases of the disease would not come under these two headings.

The British Trench Fever Commission, in their preliminary Report[5], made three classes of the disease:

A. Relapsing at (1) regular or (2) irregular intervals.
B. Single short bout, and no relapse, resembling influenza.
C. Prolonged initial fever, resembling in type typhoid or paratyphoid fever.

The American Trench Fever Commission called attention to the difficulty of making all cases fit into these or any classes, and a study of the charts of their artificially-produced cases shows the truth of this.

The intermittent "spiked" type, McNee's long type (chart 2), is very characteristic, but many of the others cannot be diagnosed clinically from the mere inspection of the temperature charts.

A. Pagenstecker[11] described four irregular types,

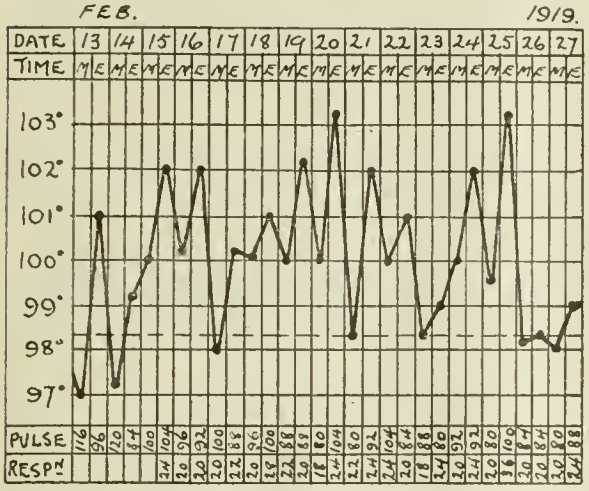

CHART 1.—Private H. This is an example of the "short type" of trench fever.

as follows: (1) In the majority of cases the febrile bouts occur at intervals of two to five days and extend over several weeks; the initial rise to 102° or higher is almost always followed by a critical fall on the next day, and then an apyrexial period with some slight irregularities supervenes until the next bout of fever. The height of temperature reached is always less than the previous one. (2) The second type resembles the first form, except that the temperature takes some days to fall by lysis. (3) In the third type the temperature suddenly runs up to 104° or more, at a time when the individual feels perfectly well: next day there is a fall of temperature with profuse sweating. In the majority of these cases the blood is naturally examined for the malarial organism, with negative results.

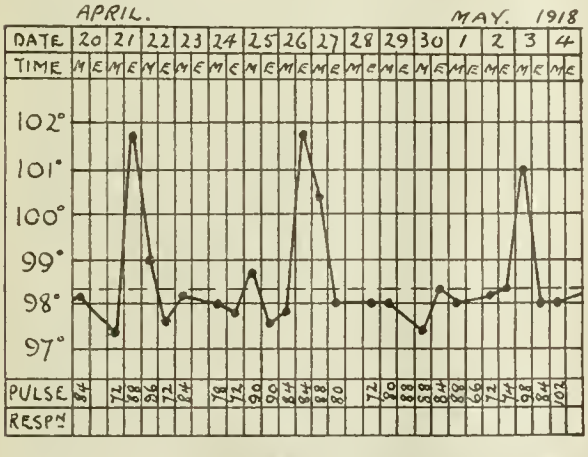

CHART 2.—This patient was invalided from France the day before this chart commences, but had been "sick" for some weeks with recurring attacks of fever. This chart shows the typical "spiked" type of trench fever; it is the "long" type of McNee.

(4) The fourth type is marked by continued fever always below 100.5°, lasting for weeks or months, and with marked subjective symptoms of trench fever. These four irregular types account for more cases than the typical disease and manifest the same symptoms, with occasionally some splenic enlargement. It is this fourth type that one see so much of in convalescent camps and amongst men of low categories, and it is the one that after the war it will be most important to recognize. On account of its resemblance to chronic malaria the writer[11] ventured some months ago to give it the name of Trench Fever Cachexia. For months, and even years the patient remains in a low state of health, with slight occasional or constant rises in temperature, often an enlarged spleen, with some anemia and pains in various parts of the body.

The American Trench Fever Commission report upon this type, as follows: "In contradistinction to ordinary infections, trench fever is characterized by its tendency to relapse, by freedom from symptoms and signs between the relapses, in many cases by long persistence of the infection and in a few cases by distinct relapses with long intervals of apparent normality". This relapsing type is, of course, well recognized, and is indeed, the long type originally described by McNee, but the Commission go on to say, "Failure to recognize the persistence of the infection has led to a disregard of slight fever, such as 99° to 99.5°F. In most hospitals the temperature is neither taken every four hours nor frequently enough to detect short relapses. The pulse rate, although taken, is often not recorded. No doubt every Medical Officer who has had much experience at the Base Hospitals has been struck by the number of patients who give a history of a previous illness which was probably trench fever, and who at the time of examination showed tachycardia, slight pyrexia, and some other slight symptoms of trench fever. All these probably point to a continuance of the infection". It is to this very common type that we would give the name of trench fever cachexia, and although, as the Commission says, it is not common for infections to relapse, exactly the same relapses and often chronic persistence is seen in malaria, and it will be shown later in how many ways trench fever resembles this protozoon infection.

We do not yet know how long these cachectic cases may last. Colonel A. B. Soltau[10] speaks of having followed them for four years. He refers to them as the "smouldering" type of the disease, and says that after a man has had an acute attack, "the infection has smouldered on, causing debility, and accompanied by an irregular temperature, occasionally running up to 100° at night, but always down in the morning. It is this type of case which is so commonly diagnosed as 'myalgia', whereas true myalgia is exceedingly uncommon. Only careful examination of the temperature curve, and the type of pain will enable a correct diagnosis to be arrived at."

At one of our special hospitals in England, devoted to the care of myalgic cases, I had the temperatures of all the patients taken very carefully, and found that some 15 per cent of these were slightly elevated at some time in the 24 hours; and examination of the patients showed that probably most of them were examples of trench fever cachexia. Quite as large a percentage was shown at another hospital for "D. A. H." cases. Many of these men had been away from the Front for over a year, doing low category work in Eng-

land, and often going sick and requiring hospital treatment. Very many had been invalided to Canada under such diagnosis as "Debility", "Anaemia", "D. A. H.", and "Myalgia". Many of them would return to homes where the body louse is a regular inhabitant, and no doubt the disease will thus be spread amongst the civil population. Major Byam, of the Hampstead Trench Fever Commission, found that lice could be infected from chronic cases up to 79 days' duration. Already we are getting some cases occurring in our camps in England amongst men who have never been abroad, but who have associated with returned soldiers.

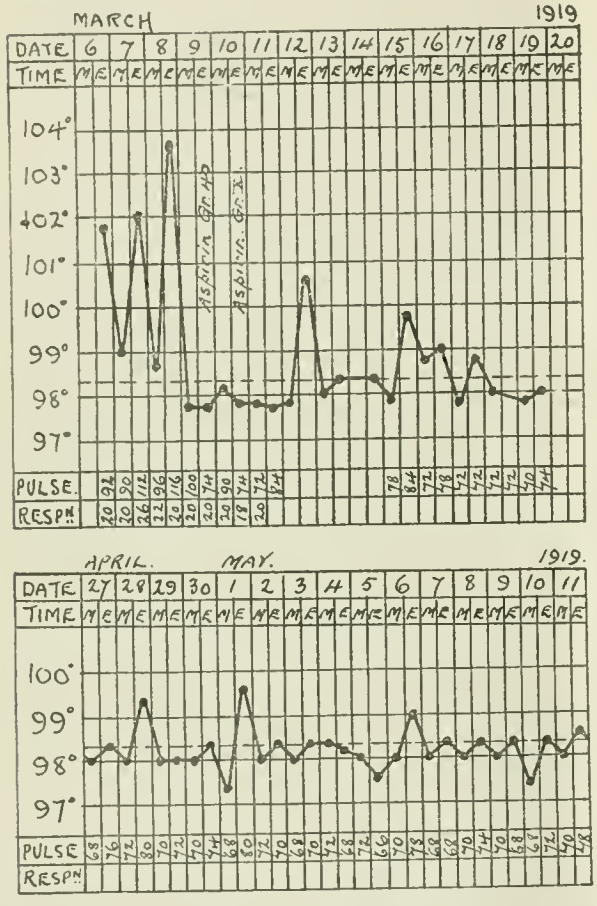

CHART 3.—Captain H. This officer had not been in any area of war. He came over from Canada some months ago and was posted in a camp in England where there were many soldiers who had returned from France. He was lousy on several occasions. Shortly after leaving this camp he became feverish, as shown in the upper chart, with great pain in the shins and soon a palpable spleen. He soon recovered sufficiently to go on medical duty, but has not been quite well since and every few days has slight fever and aching shins. The lower chart shows the slight fever of a distinctly "spiked" type. Note the effect of aspirin in the upper chart.

Chart 3 is from an Officer who had served in such a Camp and had come straight from Canada to it. He had on several occasions found lice on his clothing. He had all the symptoms typically present, including specially the shin pains.

The chronic type may occur in several forms:

(*a*) Slight almost continual fever. The cases illustrated by charts 4, 5, 6 and 7 are examples of this form.

(*b*) A form in which the temperature may seldom go above the normal line, but shows an unusual swinging of the curve so that it may be 96° or lower in the morning and 99° at night. Chart 8 illustrates the temperature course in a case of this type.

(*c*) A third form, in which the temperature chart may show no abnormality and yet the patient may have a history of an acute attack, and ever since

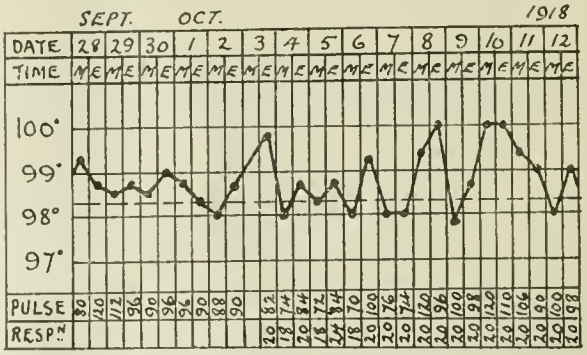

CHART 4.—Private S. Took ill in France on July 28 and was invalided to England as "trench fever." Since then until the time that this chart was made has felt poorly with aching shins. Temperature has remained up on the average about two degrees, with no definite intermissions. No local cause for the pain in the tibiæ could be found.

has had the shin and other pains and perhaps palpitation, and enlarged spleen, and other evidence that he has not completely recovered.

These last two forms may be called the "apyrexial types of trench fever".

Onset.—The onset of trench fever is usually sudden, although occasionally the patient states that for some days previously he has not been feeling himself, and has had headache and pains in various parts of the body. The temperature rises rapidly, very suggestive of influenza, although the sufferer does not as a rule seem ill in proportion to the amount of fever that is present.

The fever is frequently accompanied or followed by profuse sweating,—so much indeed is this the case that some have argued that we are really dealing with the old sweating sickness of the middle ages. Osler[20] mentions an epidemic which occurred in France in 1887, where a large number of persons were attacked. Many of these cases were slight, and may, indeed, have been trench fever, but some were "severe, with delirium, high fever profound prostration and hemorrhage" and hence present no resemblance to this disease, at any rate as we now see it.

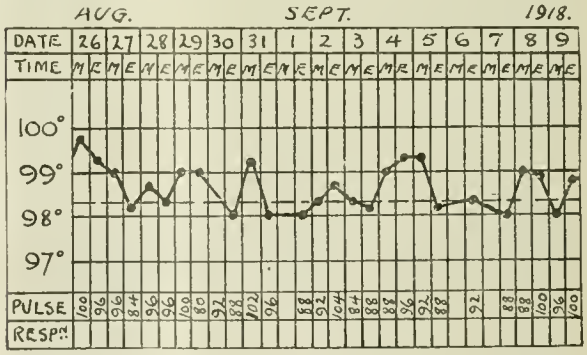

CHART 5.—Private J. M. This is the same patient as in Chart 2, only taken four months later. The case has now become one of the "cachectic" type. The chief complaint now is aching in the shins at night.

Eruptions.—In the majority of cases a rash soon appears. This usually consists (G. H. Drummond)" of 1 to 100 red spots not raised above the surface. They occur chiefly on the chest, back, and abdomen,

and last from 12 to 30 hours. Herpes may be seen.

A. Schmincke[22] found a lymphocytic infiltration, with a few polymorphonuclear cells around the dilated vessels in the eruption. This, it will be remembered, is very much the same condition as is found in typhus fever.

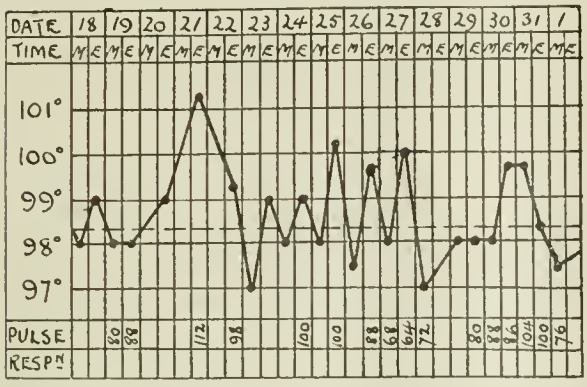

CHART 6.—Private H. This man was invalided from France on May 23 last and had been ill for several days before he "went sick." Since reaching England has been poorly, with headache and aching shins and back, all the pains being worse at night. No local condition found to account for the pain. Temperature has been running as in chart ever since his arrival in England, i.e., over three months.

When the sweating has been profuse a sudaminal rash is very common.

Pains.—Next to the fever the pains are the most characteristic symptom of this disease. At the onset headache is practically constant and is often severe, and may even be suggestive of meningitis. It may be generalised or occipital. It tends to recur with each relapse, but not to the same degree as at first. The head is often peculiarly tender, especially in the supraorbital region, and the eyes ache.

Lumbar pain comes next in frequency and resembles lumbago, and there may be much tenderness in that region.

Abdominal pain is common, and occasionally patients have been subjected to appendicectomy when the condition was really trench fever. For example, E. Graftenberg[23] reports the case of a soldier aged 22 years, who was suddenly seized with acute pain

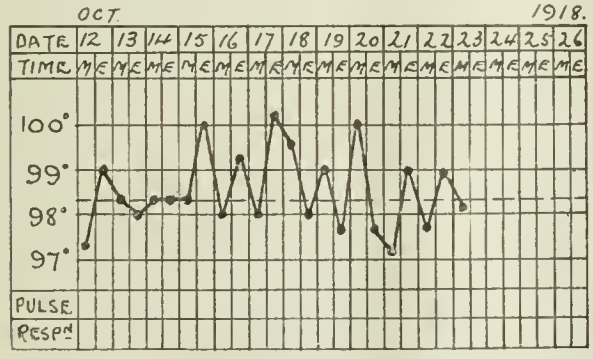

CHART 7.—Private G. This man was invalided from France a year ago as "trench fever." He had been poorly for several weeks before leaving that country. Has been feeling out of sorts ever since, with aching shins and shortness of breath on exertion. His Medical History Sheet shows that he has been in various hospitals and has always had slight fever. The chart illustrates the slight chronic type of fever.

and tenderness in the right iliac fossa, fever up to 103°, and rapid pulse (144). The appendix, which was normal, except for the presence of a stercolith, was removed, and the temperature fell to normal. Five days later the pain in the iliac fossa recurred, and for 24 hours there was fever (101.4°); two more, though slighter, relapses followed at intervals of five and six days before the patient passed from observation. The pain and tenderness, however, are chiefly superficial, and the pain is made markedly worse by putting the abdominal muscles in action, as in raising from the lying to the sitting posture.

Pains may occur anywhere in the extremities, but are so common in the shins that the disease has been called "shin fever" or "gaiter fever". In my experience this is the commonest form of pain, and it is accompanied by very great tenderness along the outer edge of the tibiæ. Occasionally one sees this tenderness so great that the patient begs that the bed clothes may be kept off his limbs by a guard. On rare occasions there is some swelling and even edema of the tissues over the painful shins. I have notes of one case where this was observed during several relapses. The exact pathology of the condition is not known. It has been attributed to a periostitis, and some writers have described microscopic changes in portions of the tibial periosteum removed for examination.

"To decide the question whether objective

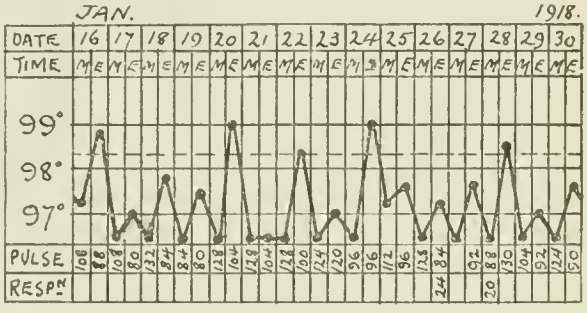

CHART 8.—Private J. H. A. This patient was invalided from France several months before with "trench fever" and has been poorly ever since, with anemia and aching shins. His chart shows the type of chronic disease where the temperature swings greatly, but is not much above the normal.

changes are to be found in the tibiæ in trench fever and other febrile diseases associated with tibialgia, and whether such changes are due to the disease or whether they were present before, Burchard made an *x*-ray examination of a number of cases of trench fever and other conditions. Of 32 cases of pure quintan fever, 22 had well-marked spontaneous pains in the tibiæ; 3 complained of pain on pressure only; 6 had diffuse pain in the legs, and only 1 had no pain whatever in the legs. In almost all these cases the *x*-rays showed a more or less well-marked periostitis in the diaphyses of the tibiæ, less frequently in the fibulae and occasionally also in the bones of the forearm. The severity of the pain was by no means always in proportion to the periostitis present. The patients complained of severe pain when there were little or no changes visible, and on the other hand, a patient in whom definite periosteal changes were present did not complain at all. The skiagrams showed that the periosteum alone was affected. Similar lesions were found in 14 cases of trench fever, with an atypical temperature chart. An examination was then made of 37 soldiers who had been sent to the *x*-ray department for wounds or diseases unconnected with pains in

the legs, and in about half the cases identical changes were found in the periosteum. A comparison of the three groups of cases showed a striking frequency of periosteal changes in quintan fever and other febrile diseases accompanied by tibialgia. On the other hand, the skiagrams did not show anything characteristic, so that the supposition that periostitis was a consequence of the infectious disease was improbable. Burchard thinks it much more probable that the periostitis had been in existence before and that the pain was due to the supervention of the infectious disease."[24]

J. Blesch[25] protested against the view held by many that shin pain was a *sine qua non* for the diagnosis of trench fever. He thought that probably marching with heavy kit made the tibia a *locus minoris resistentiæ*, and any affection, such as influenza, enteric, malaria, relapsing fever, or gonorrhea, may cause pain here. He confirmed Queckenstett's observations that such pain often followed vaccination for enteric, smallpox, or cholera.

All the same, I think that few clinicians of experience will now deny that the shin pains are peculiarly common and agonizing in trench fever—more so, indeed, than in any other infection. The pains are nearly always worse at night and are described variously as aching, burning, dragging, etc. I quite agree with the above writers that the probable reason why the shins are so often attacked is that the heavy marching has caused some fibrositis here, and then the infection or toxemia attacks this damaged area. In support of this view one may quote the fact that trench fever patients constantly tell us that they get pain in any old wound site, fracture, or strained joint or tissue. In the late stages these cases are often diagnosed as "myalgia." Captain Chevasse and Marr (Letter of Colonel Soltau[19]) independently examined many cases of "myalgia," and the former believed that 43 per cent. were really trench fever and the latter 70 per cent., and Colonel Soltau would put the figure as high as 80 per cent As already stated, I found that 15 per cent. of very late cases of myalgia studied in England were probably of this nature, and even still had some fever.

Blood.—The blood picture is variable, but usually there is a moderate leucocytosis during the fever. According to H. Perkins and R. H. Urwick,[26] who made a special study of the hemotology of the disease, there is a marked rise in the leucocytes of all kinds at the time of the febrile relapse, and a gradual relative rise in the lymphocytes during convalescence. The American Trench Fever Commission found the extreme ranges of the white count was from 3,400 to 27,000 and a majority of their cases gave a count of from 13,000 to 17,000.

It must be borne in mind, however, that the white cell count tends to be higher in soldiers than in civilians. Several observers have noted this peculiar fact. Thus Bokelmann and Nassau[27] examined the blood of 70 healthy soldiers (officers and men), 59 being of middle age. There was a well-marked increase in the lymphocytes, varying from 25 to 73 per cent. and averaging 43 per cent., with a corresponding diminution in the polymorphonuclear cells. S. Newman[28] found the same thing, as did also D. L. Tate and J. W. McLeod[29]. With this qualification, a rise in the leucocytes may then help in the diagnosis of trench fever as against typhoid, but an absence of this leucocytosis will be of no value.

Professor Duncan Graham tells me he has found that the chief difference between the blood picture in malaria and in trench fever is that in the former the blood platelets are absent, while in the latter they are numerous. I have not come across any mention of this in the literature.

Circulation.—During the fever the pulse rises in proportion to the temperature. Accurate watching of the heart in this stage of the disease often reveals a temporary displacement of the apex to the left. Such may be seen in any infection, and there is no evidence that the virus of trench fever in any way specially attacks the heart muscle or its membranes.

But functional disturbance of the heart is very common after trench fever. In an inquiry into the cardiac manifestations of trench fever, J. Fischer[30] found that among 807 patients 8 per cent complained of symptoms, such as pain and oppression in the left side of the chest, palpitation and dyspnea, and that all these patients had objective signs, such as rapid pulse, a raised blood pressure (up to but not beyond 160 mm. Hg.), arrhythmia, mainly respiratory, slight cardiac enlargement, and a systolic murmur at the apex or over the pulmonary artery. Patients never showed the acute cardiac failure or vasomotor paralysis seen in other acute infections. Further, the arrhythmia was never of a type to justify a diagnosis of myocarditis. He thought the cardiac disturbances were not myocardial, but nervous. They occurred in patients of weakly and poor muscular development, and predisposition was probably a factor in their development. Fortunately, trench fever is not a fatal illness, and hence we have no post mortem reports of the actual condition of the heart, but clinically the condition is suggestive rather of a nervous than of an organic heart lesion.

Again, it must be remembered that trench fever is the commonest of all infections at the Front, and hence many cases of "D. A. H." will naturally give a history of it. The American Trench Fever Commission in their experimental work selected only men of a fine physique, and in no instance did they find that any "D. A. H." occurred after the infection was over. Occasionally the "effect syndrome" was detected, but it was always found that the infection was still present, and when this finally disappeared, so did the circulatory symptoms. It should be noted in this relation that the staff of the special Heart Hospital at Colchester reported that slight fever is often present in "D. A. H." "D. A. H." is probably cardiac neurasthenia, and it is easy to see how such would be intensified by any infection, and hence we get the history of it so commonly dating from the commonest of all infections, *i.e.* trench fever. Further, a careful inquiry nearly always shows that the circulatory symptoms preceded the fever and were only intensified by it.

But one would like to repeat that trench fever is often a very chronic condition, and to express the opinion that many cases of "D. A. H." are examples of a still present infection. This is very important, for such cases require rest rather than exercises as long as any activity is present.

Respiratory System.—There are no special respiratory symptoms in trench fever. Often one gets

a history of some cough and slight sore throat, but these are so common in soldiers that they are of little significance.

Gastrointestinal symptoms are not characteristic in any way, although there may occasionally be some nausea and even vomiting at the onset of the disease. W. Buckbinder[31] drew attention to a triangular zone, with the base at the uvula and the apex pointing forward, in which the mucous membrane shows a number of injected vessels, vesicles and some hemorrhagic spots. R. Fleck[32] observed the same thing in 18 cases of quintan fever (which is probably just another name for trench fever), and in 10 cases of skin disease without fever from the same battalion. As the pains in the shins were exactly alike in both groups of cases he assumed that they were due to the same factor, viz., trench fever infection. This last afebrile group would correspond to our Class C of the chronic type. As already mentioned, occasionally the pain in trench fever is so localized in the abdomen as to suggest local disease there.

Urine.—In the acute stage the urine may contain a little albumin, but the strain upon the kidneys does not appear to be great, and the albumin soon clears up. The urine may show large quantities of indican during the fever, which is probably due to proteolysis, as there is not usually much intestinal disturbance. "Excessive urobilinogen is absent, and this is interesting on account of the resemblance of trench fever to malaria, in which latter disease urobilinogenuria is said to be constant." (*Med. Supplement*, 1918, 1, 29, 212.)

Nervous System.—The pains, which are such a striking feature of trench fever, seem rather to be of peripheral than of central origin, although some writers, for example Prof. Sims Woodhead,[33] consider them as being referred and due to excitation of nerve cells in the spinal cord. At the onset of the fever, as already mentioned, headache is very common. Giddiness may also occur.

As regards the eyes, pink eye, a sensation of sand in the eyes, misty vision and nystagmus, are all common early in the disease. (H. Drummond[34].) The reflexes, both cutaneous and muscular, are, as a rule, increased, but otherwise not altered.

Last autumn, Major D. W. Carmalt Jones[34] described a peculiar condition of cutaneous hyperesthesia that often occurred in trench fever cases. These are of a similar nature to the areas of cutaneous hyperesthesia that have been so minutely described by Sir J. Mackenzie and Dr. H. Head as indicative of disease of various organs of the body, only the distribution is different. Major Carmalt Jones examined in a routine manner all the patients coming into a base hospital in France. Definite segmental areas of increased sensibility to pain were found very constantly, corresponding to diseased viscera, but in a number of cases the distribution did not correspond with any viscus. These unusual areas were the margins of the areas supplied by the eighth cervical and first dorsal, the seventh dorsal, and all the lumbar segments of the cord. When all the patients showing such distribution of hyperesthesia were investigated further, they were found to be examples either of malaria or of trench fever.

Capt. C. E. Sundell,[35] in discussing Major C. Jones' findings, confirmed them, but also described areas of anesthesia to pin prick within the zones supplied by these nerves. These areas were most common on the outer part of the calf, the infrapatellar, scapular, and deltoid regions.

I have examined many cases of trench fever in regard to these areas of hyperesthesia, and have very often found them present, although I am not so sure of Sundell's areas of analgesia. I have demonstrated the symptom in some cases of "D. A. H.' and also of myalgia, and consider that it is a valuable aid in the detection of chronic and doubtful cases of trench fever.

Prognosis.—The prognosis as regards life seems to be absolutely good in trench fever. No definite case has been described where a fatal issue occurred. Some few instances appear in the literature where death has supervened, but a careful examination of the descriptions of these cases suggests that some other factor had to do with the result.

The chief difficulty in the prognosis is to say how long the condition is likely to continue. Many cases of trench fever consist of a sharp attack, like influenza or modified typhoid or paratyphoid fever, and the patient remains well afterward. The "spiked" cases are apt to recur again and again for some weeks or even months. When once the fever has assumed the cachectic type it may go on for months and years, being specially apt to flare up into an acute attack when the patient undergoes any traumatism or other nervous strain. We have yet to learn how many years some of these cases may continue.

Treatment.—It may be said in a word that up to now no satisfactory treatment of trench fever has been found. A great many things have been tried and each has had its advocate, but further trial by others always leads one to the conclusion that we have very little power in checking the infection. Schneyer[36] stated that he used methylene blue successfully. He gave 12 cases 4 grains on the morning and the afternoon of the day before that on which a recurrence was expected, three similar doses on the actual day, and one on the day after. The fever did not recur and no toxic symptoms were noted.

Sodium salicylate has been extensively used and it seems to have some influence in lessening the fever, and certainly gives some symptomatic relief. Du Mont[37] found that a single massive dose of this drug (1½-2 drachms), if given on the morning of the expected attack, produced profuse sweating, and the fever did not occur. Others have been content to use smaller doses more frequently.

Collargol in 1 to 2 per cent solution intravenously has been advocated. We have tried it in several cases and got no good results, but a great rise in temperature and some depression.

Quinine appears to control the condition somewhat, but is often disappointing.

Salvarsan and all the newer preparations of a similar nature have been used, but the results are not convincing.

Therefore we must fall back on symptomatic therapy and can thus give a certain amount of relief. When there is any fever the patient should be kept in bed. Salicin or sodium salicylate in doses of ten to twenty grains every four hours gives some

relief. Or aspirin may be used in half these doses. (Chart 3 shows the influence of aspirin on the fever.) When there is much local pain, heat tends to ease it. Sometimes gentle rubbing in of some liniment, such as the *linimentum belladonnæ*, eases the suffering. Between the attacks and during the chronic stage gentle exercise is valuable in improving the general health. As long as there is any reason to suspect that the infection is still present, the patient is not fit for any but the lowest category of military duty.

Centenarians in California.—The number of centenarians in this State of 3,000,000 inhabitants is said to be over 300. This high figure is attributed to pure air, fertile soil, and moderate temperature.—*Le Progrès Médical.*

Medicolegal Notes.

Cause of Accident—Injury or Disease?—In proceedings for compensation for death by an alleged elevator accident, the evidence of the attending doctor was, in substance, that the deceased, who had been suffering from rupture for seven years, informed him, when he was called to his attendance within about an hour after the alleged accident, that the drop of the elevator hurt him, and that when he examined the injured intestine and the imperfect rupture truss the deceased wore he concluded that the shock caused by the drop of the elevator was the primary cause of the injury to the intestine. This evidence was held to be of such substantial character that a reasonable conclusion could be drawn therefrom that the injury was proximately caused by the accident.—F. Eggers Veneer Seating Co. v. Commission, Wisconsin Supreme Court, 170 N. W. 280.

Validity of Order Revoking License to Practise.—The Illinois Supreme Court holds that the power given by the Civil Administrative Code to the department of registration and education to revoke a license to practise medicine within the State is not arbitrary. The department cannot act except for cause shown, upon notice and hearing, and with an opportunity to defend. Its power to revoke the license of a medical practitioner cannot be exercised except upon the action and report in writing of a majority of the five reputable physicians licensed to practise medicine and surgery in the state designated from time to time by the director of registration and education for that purpose. It is essential to the validity of an order revoking a license that it shall show the facts essential to the jurisdiction of the department.—Blunt v. Shepardson (Ill.), 121 N. E. 263.

Sunstroke "Personal Injury" Within Workmen's Compensation Act.—In proceedings under the Connecticut Workmen's Compensation Act for the death of an employee by sunstroke sustained while shoveling coal on a hot day, it was held that under that act sunstroke is a compensable injury. The trial court found that the sunstroke paralyzed a definite portion of the deceased's brain, so that it no longer discharged its proper function in connection with the distribution of heat in his body; as a consequence, his temperature rapidly rose, and death directly resulted in accordance with the ordinary progress of such a disturbance of the brain. The appellate court held that this finding pointed out a bodily harm and incapacity of the deceased, and indicated a localized, abnormal condition of body. It brought the sunstroke directly within the court's definition of a personal injury under the act, 91 Conn. 162. This untoward event or unexpected condition under which the deceased's work was carried on therefore constituted an accident which directly and contemporaneously caused this localized abnormal condition. As it clearly appeared that the deceased, when stricken, was doing what he was employed to do, the sunstroke arose "in the course of and out of his employment," within the act. The fact that he was not exposed to sunstroke in greater degree than others in the same employment, and than many other out-of-door workers, was held immaterial.—Ahern v. Spier, Connecticut Supreme Court of Errors, 105 Atl. 340.

Waiver of Warranty by Medical Examiner.—A local medical examiner of a fraternal beneficiary association, who is not an officer of the local lodge, but an agent of the supreme body, can waive warranties in the application for insurance.—Hereford v. Mystic Wonder Workers, etc., (Mo.) 207 S. W. 76.

Accident Insurance—Warranty as to Medical Attention.—An insurer cannot be deemed to have waived a breach of a warranty contained in an application that the insured had not received medical attention within two years, because its agent and physician had notice or knowledge of the breach where the policy expressly withheld from such agents authority to change the policy or to waive any of its provisions, and provided that notice to such agents or knowledge of theirs should not be held to effect a waiver of the contract or any part of it. The terms of the contract were such as to make the truth of the plaintiff's statement a condition precedent to his recovery. It was in express terms made a warranty.—Maryland Casualty Co. v. Campbell, 255 Fed. 437.

PHLYCTENULAR KERATOCONJUNCTIVITIS.

PHLYCTENULAR keratoconjunctivitis is a mild ocular process with a tendency to spontaneous cure, but subject to frequent recurrences. The lesions are usually seated over the limbus corneæ and malignant forms of the affection are exceptional. It is met with more commonly in little girls than boys. Rare during the first year of life, its maximum of frequency is reached between the the ages of two and six years, after which it progressively decreases up to the twentieth year. After the age of thirty it is exceptional (Maggi). The process appears in April and reaches its maximum in May and June. It is an affection of the poorer classes and is observed, according to Fukala, more commonly in hospital practice, but it occurs among the better class as well. It is prone to coexist with various scrofulotuberculous affections, likewise in rhinopharyngeal infections and impetigo of the face and scalp. It has been termed scrofulous ophthalmia by some, impetiginous keratoconjunctivitis by others.

The etiological factors have been sought for in the presence of external causes, such as foreign bodies or neighboring infections, but both clinically and experimentally it has been conclusively shown that these are not enough to produce the process. At the most, it may perhaps be admitted, as Maggi believes, that the patient offers a special soil, usually tuberculous. Whenever a rhinopharyngeal affection coexists with phlyctenular keratitis, the evolution of both processes goes hand in hand, as is noted by their simultaneous cure or recurrence, consequently, a rhinological examination of all cases of phlyctenular keratoconjunctivitis should be made whenever there is any doubt as to the condition of the nose or pharynx.

The subjects of this affection react to tuberculin in the proportion of about 93 per cent., and a minute clinical examination will reveal lymphatic or visceral lesions of a torpid character in most of them, but the ocular process is seldom or never encountered in phthisical subjects. Experimentally, the slightest positive result has never been obtained by inoculation of the phlyctena into the anterior chamber of the eye of the rabbit, guinea-pig, or monkey. The experiments undertaken by Terrieu only confirm those of different writers who have studied the subject. An absolutely negative result has always so far been obtained in attempts at experimental reproduction of the phlyctenæ.

Dor of Lyons places phlyctenular keratitis in the class of tuberculides, due to the diffusible toxins of the bacillus of tuberculosis, while other writers believe that the process is due to the irritating local action of the bacilli of tuberculosis having an attenuated virulence on account of their small number, their special strain, or their death.

It is to be hoped that future researches will finally show whether phlyctenular keratitis should be definitely looked upon as a manifestation of an attenuated bacillosis or if it is a benign process undergoing its evolution on a scrofulotuberculous soil; but until further progress in the pathogenesis of the disease has been made, an endogenous origin should be accepted as probably the true one.

THE PROGNOSIS OF ALBUMINURIA IN PREGNANCY.

THE appearance of albumin in the early months of pregnancy, its large amount, and its persistance during weeks or months following labor, would seem to indicate a particularly serious prognosis, but experience shows that this is not necessarily the case. It is enough to go over certain case-histories to be convinced that women who have had much albumin, which did not disappear from the urine for six months after delivery, nevertheless had future pregnancies without albuminuria. Generally speaking, the prognosis is more serious when albumin occurs in multiparæ who have presented nothing abnormal in their former pregnancies, and in them it would seem that the albumin is more the result of a former bad condition of the liver and kidneys, rather than of the action of the pregnancy itself. On the other hand, in primiparæ the hepatic and renal lesions, which may be grave, even fatal, are usually temporary, are produced by an intoxication of gravidism, and do not manifest themselves in future pregnancies with the same intensity because the organism is, so to speak, immune.

The ultimate prognosis of albuminuria in multiparæ would, consequently, appear to be bad, but it is to be remarked that many women—particularly among the working classes—do not always consult the physician early enough for treatment of accidents of autointoxication, so that proper therapeutic measures are not instituted in time. They come to the hospital when a symptom, such as edema of the lower limbs or hemorrhage, occurs. Unquestionably, a number of women when duly warned will submit to medical care in their future pregnancies and thus avoid the return of more or less serious accidents, but there are also many who take no heed of the warning given.

From present statistics it seems fair to conclude that a woman presenting albuminuria in her first pregnancy is not fatally destined to have it in her future gestations, but when a woman has had al-

lumin in the urine with her first pregnancy and this is again present with the second, the pregnancy will rarely go to term if the mother is not medically supervised. The urine should be examined at least once a week in all cases where accidents of autointoxication have occurred during a former pregnancy, and once a month a complete analysis should be made. The obstetrical prognosis of the albuminurias of pregnancy is all the more favorable, the greater the medical care given during gestation, the greater the thoroughness with which both diet and other necessary treatment are carried out.

WOMEN WORKERS.

THE present war has proved, as it never has been demonstrated before, the great value of female labor. Many of the long held views with regard to the limited scope of such labor have been shown to be fallacious. Perhaps it may be thought by some that the tendency now is to place an exaggerated value on the capacity of women for all kinds of manual and mental labor. However, judging from the remarkable way in which women have acted as substitutes for men during the war it seems almost impossible to put any limits on their powers of endurance and capability for performing tasks usually allotted to men. It has become a truism to state that women shine in the professions and especially in that of medicine. Medical women have borne their part nobly in the war, but it is not in the professions alone that woman has made her mark. In many trades and in work of various and arduous kinds she has emphasized her ability to compete with man. Undoubtedly, she is to some extent physiologically handicapped, but apparently this handicap is not nearly so great as it has been thought to be. If personal hygiene be properly attended to, a proper diet be adhered to, and vitality be kept up to a high standard, the physiological disabilities of women, *pace* Sir Almroth Wright, may be largely overcome. As Dr. Janet Campbell points out in a memorandum dealing with the health of women, contained in a report of the British War Cabinet Committee published recently, the results of employment of women under war conditions have lent weight to the importance of health, of good food, clothing, and domestic comfort which can be obtained when the wages represent a reasonably adequate recompense for labor. They have also proved that adequately nourished women have a much greater reserve of energy than they have usually been credited with, and that under suitable conditions they can properly and advantageously be employed in more arduous occupations than has been considered desirable in the past, even when these involve considerable activity, physical strain, and exposure to weather.

The influence of industrial employment on motherhood and on infant mortality is not good in itself. While it is obvious, however, that prolonged, fatiguing work must be prejudicial to motherhood and favor a high infantile mortality, yet it would seem that the most important influences are poverty, bad housing, and insanitation. Poverty and bad housing are often inseparable; ill-paid work and a low standard of domestic hygiene are usually, though not always, associated. A hand-fed baby is much less likely to thrive in such circumstances than in a well-to-do household. Industrial employment influences infant mortality mainly because it leads to the neglect of breast feeding. Further, the infant may be left in charge of an unskilled "minder" instead of being sent to a properly managed crèche. Taking into consideration then the pros and cons with respect to the employment of women, it appears that, on the whole, the fors are stronger than the againsts.

The contention that woman is so much the weaker vessel is not borne out by history. In the old days and among primitive communities at the present time, the greater part of the work was and is done by the women. During the war, not only on the continent, where a good deal of the agricultural labor has always been done by women, but also in Great Britain the farm work was practically all done by them. Consequently the verdict of those who have investigated the matter is that provided a healthy woman is well fed, well housed, and does not work too long or too hard, she can perform succesfully many kinds of labor, and her labor is a valuable economic asset to any country.

THE CYCLE OF CHOLESTEREMIA.

BY applying certain unquestionably exact chemical methods in the dosage of cholesterin to clinical and physiological researches, Chauffard, Grigaut, and Laroche have been able to collect a number of reliable data relating to the cycle of cholesteremia. The percentage of cholesterin normally circulating in the human blood-serum varies between 140 cg. to 190 cg., so that 160 cg. may be regarded as the mean normal amount of cholesteremia in man.

The proportion of cholesterin in the blood-serum undergoes important changes during gestation and various pathological states. It is increased during pregnancy and the puerperium. It is very low during the period of full development of the infections, while during the period of convalescence it is, on the contrary, above normal. Hypercholesteremia is often considerable during icterus or Bright's disease, the proportion of cholesterin attaining sometimes more than fifteen grams per liter. Hypercholesteremia is not the rule in diabetes; it is subordinated to the lipemia that it frequently accompanies.

The data obtained from the blood-serum are quite in accord with what these writers observed in certain endocrine glands, and clinical data combined with experimental work have led them to regard the suprarenal glands and corpus luteum as the two important centers of cholesterogenesis and the

principal origins of the cholesterin of the blood-serum. The direct alimentary supply is only accessory in the genesis of cholesteremia, which is chiefly of endogenous origin. The hypercholesteremia of renal patients and pregnant women is, therefore, a hypercholesteremia from hypergenesis.

As to the destiny of the cholesterin of the blood-serum, these writers, and Grigaut in particular, have demonstrated the undeniable part played by the liver in the metabolism of this product. Cholesterin is normally eliminated by the liver, but in Grigaut's opinion only a very small quantity is thus eliminated in the form of cholesterin, the greater proportion appearing in the bile in the form of a transformation product, namely, cholalic acid. Cholesterin thus contributes to form the nucleus of the biliary salts. In case of disturbance of the biliary function of the liver, the cholesterin is retained in the organism, and the hypercholesteremia which then ensues is a retention cholesteremia and should be placed in the syndrome of biliary retention.

Leprosy in Brazil.

A careful survey of the lepers of the Brazilian State of Para throws some new light on the nature of this affection as a social disease. In the *Brazil-Medico* for May 3 Aben Atar first refers to the original leprosorium in this State, erected in 1816. The disease had apparently been introduced by early Portuguese colonists. The hospital admissions seem to have varied greatly of recent years. Thus in 1901 there were but 17 admissions, while in 1918 the number was 112. In 1914 the number was 100, which was very much higher than any previous recent statistical year, but this increase was evidently due to the establishment of compulsory notification; and the admissions for the next two years fell to the usual level, and as a result of lax enforcement of the law. The authorities then resumed their severity, and in 1919 the total will doubtless be much higher than ever. In addition to 112 cases in 1917 there were admitted during the first seven months of 1918 alone 92 cases. The total number of lepers at present in the institution is 882, of which 600 are males. All but 58 are Brazilians, and 457 are from Para. As to race, whites and mixed bloods make up most of the cases, the latter predominating somewhat. Full-blooded black people make up only 10 per cent. At least one-third are less than 20 years of age, which speaks for early infection, while control of the entire material shows that a majority of the infections begin in childhood or adolescence. These ages show diminished resistance, and argue also for a natural or acquired immunity which most people possess. A careful analysis seems to show that so far as Para goes, the disease may be termed one of childhood. The great majority of those who escape infection are probably not endowed with any general natural immunity, but have been protected, like the majority exposed to tuberculosis, by silent and minimal attacks of infection which confer immunity; or, in other words, by autovaccination. In consequence, the adult becomes relatively immune. The author's thesis might have been made stronger by giving the relative numbers of mild and severe lepers, for if an immunizing process is taking place there should be many cases of the nervous type. The author alludes to this view, but cites no proofs.

Chronic Vulvitis.

Both dermatology and gynecology are most unsatisfactory in dealing with this subject, which is eminently of the borderland type and in need of a new orientation. Aside from chronic gonorrhea there is hardly any condition which fits this designation and yet from analogy there should be chronic productive and post-inflammatory primary and secondary atrophic and sclerotic conditions, here as elsewhere. There are numerous conditions variously termed chronic primary and secondary pruritus, incipient kraurosis vulvae, leucoplakia, lichen planus atrophicans, lichen of Vidal, eczema, dermatitis, etc., which are hopelessly confused among themselves and may be found to merit jointly the term chronic vulvitis in addition to chronic gonorrhea and other infections. We cannot better illustrate this confusion than to quote a case mentioned in the *Correspondenz-Blatt für Schweizer Aerzte* for April 5, of a patient shown before the Swiss Dermatological Society. She was 22 years of age and in good general health and her trouble dated back two years. The affection was sharply limited to the vulvoanal region. There was and had been intense pruritus, but apparently none of the lesions could be connected with scratching. There was depigmentation of much of the pigmented area, and the nymphae showed cornification in addition to a bright red color. Biopsy showed an acanthosis and evidences of inflammation in the subjacent derma. All of the usual remedies were without effect. Lichen of every description could be excluded despite the fact that this process can cause depigmentation. The vitiligo which resulted was not present elsewhere in the body, and may have been the initial manifestation. Jadassohn has seen several cases of associated pruritus and vitiligo in the vulvoanal region but the rest of the picture was absent. The use of the term leucokeratosis for the condition of the nymphae suggests what is commonly known as leucoplakia vulvae, although this term is nowhere mentioned. Jadassohn, however, in mentioning the danger of epithelioma, must have had that condition in mind. The possibility of an initial kraurotic condition is nowhere mentioned.

News of the Week.

The First Month of Prohibition.—A recent issue of the *Literary Digest* cites statistics gathered from many cities showing the salutary effect of prohibition, though it admits that the month, strictly speaking, could scarcely be considered a "dry month." In California the effect of the first month of prohibition has been to cut the total number of arrests for all offenses by two-thirds. The arrests for drunkenness in that State have fallen to almost nil in the larger cities. In Chicago all phases of crime showed a decrease except murders, which remained stationary, and assaults which showed a slight increase. The inebriate ward at the Philadelphia General Hospital, which accommodated 3,481 cases in 1917 and

2,326 in 1918, closed its doors in July. The Philadelphia House of Correction had 302 men and 226 women inmates on July 27. This month in previous years brought an average of 1,000 men and 300 women. Boston tells the same story, fewer arrests, less illness, and fewer accidental suicidal deaths traceable to the excessive consumption of alcoholic drinks. The Boston Police Department records show that there had been a reduction of 50 per cent. in self-inflicted deaths compared with July, 1918. The New York *Tribune*, on the basis of figures prepared by the Police Department, reports a decrease of 15 per cent. in crimes of all kinds compared with July of 1918. An increase in the use of drugs is noted by the Health Department, and police officers state that drugs as a substitute for liquor make criminals harder to catch. Bellevue Hospital reports an increase of cases in the psychopathic ward for July, 1919, over July, 1918. Other New York hospitals note little change.

Women Red Cross Workers Removed from Omsk.—All the American Women Red Cross workers at Omsk, approximately sixty in number, were recently ordered to Irkutsk by Roland S. Morris, the American ambassador to Japan, who came to Omsk to make an investigation of the Kolchak government. Dr. Manget and Major MacDonald, Red Cross heads, secured a modification of this order and obtained permission to retain twelve of these workers, seeking thus to prevent complete demoralization of the 1,000 hospital-bed which the Red Cross is maintaining in Omsk. A consular train has been provided to remove the women in case of emergency.

Major-General William C. Gorgas, who has been investigating sanitary conditions in Central and South America, has offered to assume technical direction of the sanitation of Guayaquil if money for the work is supplied by the municipality or the Government of the republic. General Gorgas, at the request of the Peruvian authorities, will proceed to Pira, 210 miles from Guayaquil, which is infected with yellow fever.

Henry P. Davidson, chairman of the War Council of the American Red Cross, has been presented with the Distinguished Service Medal by Secretary of War Baker, in behalf of President Wilson, for exceptionally meritorious and distinguished services in behalf of the Government and the Red Cross during the war.

The Osler Anniversary Volumes.—The Anniversary Volumes published in honor of Sir William Osler's seventieth birthday, will be ready for delivery by October 1. Subscriptions are still being accepted and may be sent to the Treasurer of the Committee, Dr. Henry Barton Jacobs, 11 Mount Vernon Place, Baltimore, Md.

Cinchophen.—This is the name which the Chemical Foundation proposes as the simplified term for the pharmacopeial phenylcinchoninic acid, or the proprietary atophan. Among the changes made in the designation of other drugs originally manufactured under German-owned patents are arsphenamine for salvarsan, barbital for veronal, and procaine for novocaine.

America's Gift to China.—Dr. M. E. Macklin a professor at the Nanking University Medical College recently testified before a Senate committee that a traffic in opium and other narcotics is being fostered by the Japanese in China. But Japan seems not to be alone, for a dispatch to the *New York Times* from Peking states that morphine is being sent into China by American firms, the comment being made that America, having gone "dry," is sending to China a noxious drug which is responsible for the moral and physical ruin of millions of Chinese. A case of smuggling has just been heard in the Japanese consular court at Shanghai in which the evidence showed that the drug came from Philadelphia.

Vacancies for Physicians.—The Civil Service Commission of New York State announces an examination to provide eligibles for the position of Deputy Medical Examiner, Bureau of Deportation, State Hospital Commission, at a salary of $3,500 per year. An examination of also announced to provide eligibles for the position of Assistant Physician in the State hospitals and other positions of similar nature in various State and County institutions. The salary in the State hospitals is $1,200 with increase. Application forms must be obtained before September 15, 1919, and applications must be received at the office of the Civil Service Commission, Albany, N. Y., not later than September 17, 1919.

The Industrial Physicians and Surgeons of the Department of Labor and Industry of the State of Pennsylvania will hold its ninth annual conference at the State Capitol, Harrisburg, Pa., on September 22, 1919. The conference will be held in cooperation with the Medical Society of the State of Pennsylvania, which will hold its annual meeting in Harrisburg at that time.

Rockefeller Institute Commended.—The directors of the Rockefeller Institute for Medical Research have made public a letter recently received from Surgeon General Ireland expressing his thanks for their work of patriotism and generosity in placing so fully at the disposal of the Medical Department of the Army their great and productive facilities for research, for teaching, and for the care of the sick during the world war.

Rockefeller Institute Announces Promotions and Appointments.—The Board of Scientific Directors of the Rockefeller Institute for Medical Research announces that Dr. Harold L. Moss, hitherto an associate in pathology and bacteriology, and Dr Oswald T. Avery, hitherto an associate in medicine, have been made associate members. Miss Clara J. Lynch and Dr. Waro Nakahara have been made assistants in pathology and bacteriology. The following new appointments have been made: Dr. Homer J. Swift, associate member in medicine; Dr. Francis G. Blake, associate in medicine; Dr. Raymond G. Hussey, associate in pathology and bacteriology; Dr. J. Harold Austin, assistant in medicine and assistant resident physician; Dr. Albert Ebeling, assistant in experimental surgery; Dr. Ferdinand H. Haessler, assistant in pathology and bacteriology; Dr. Thodsten Ingvaldsen, assistant in chemistry; Dr. Charles W. Barrier, Dr. J. Jay Keegan, and Dr. Philip D. McMaster, fellows in pathology and bacteriology. Dr. Alphonse R. Dochez, hitherto an associate member in medicine, has accepted an appointment as associate

professor of medicine in the Medical Department of Johns Hopkins University. Dr. Arthur L. Meyer, hitherto an associate in physiology and pharmacology, has accepted an appointment as associate in physiology in the School of Hygiene and Public Health, Johns Hopkins University.

The Medical Society of the Missouri Valley will hold its thirty-second annual meeting in Des Moines, Iowa, September 18 and 19, 1919, under the presidency of Dr. Charles Wood Fassett of Kansas City. The arrangements for the meeting are in the hands of the Polk County Medical Society, Dr. Charles Ryan being chairman of the committee.

Kentucky Licenses New Physicians.—Licenses have been granted to twenty-three young physicians by the State Board of Health of Kentucky, enabling them to practice their profession in that State.

Red Cross Institute Finds Positions for Cripples.—The Red Cross Institute for the Crippled and Disabled, at 311 Fourth Avenue, New York, announces that within the past twelve months its employment bureau has placed 1,000 crippled men and boys in positions. The office is seeking to get in touch with all cripples in the city who want help in getting work and suggests that anyone knowing of such cripples can do a good service by referring them to this bureau.

Buenos Aires Bars Narcotics.—The Municipal Government of Buenos Aires has enacted stringent regulations restricting the sale of drugs to the people. The sale of narcotic drugs is prohibited except upon the presentation of a prescription prepared by a registered physician. Until this law was enacted drug stores were permitted to sell cocaine, morphine, opium, and other drugs with the greatest freedom. The Government has established dispensaries where those suffering from various diseases requiring the administration of narcotics may procure such narcotics. It is said that drug addicition has become very common in Buenos Aires and has spread to all classes of society.

A Proposed Pan-American Congress on Influenza.—A bill has been introduced into the Chamber of Deputies of Uruguay providing for the calling of a Pan-American Congress for the purpose of devising ways and means of combating influenza next winter. The leading medical men of the Latin-American republics will be invited to present papers dealing with the causes and preventive measures to be taken against the disease. Eminent medical men from the United States and Europe will also be invited to participate. It is planned to hold the congress in Montevideo. One of the purposes of the congress will be to formulate measures of a uniform nature for adoption by all the countries.

Church Seeks Physician for Hospital in Japan.—The Board of Missions of the Protestant Episcopal Church announces that it is looking for a young physician with suitable qualifications to go into the interior of Japan to establish and supervise a small missionary hospital. The funds for a thirty-bed hospital have been donated by a wealthy Japanese who stipulates that the hospital must be Christian and under Christian direction.

Typhus Suspect on Italian Liner.—The discovery of a suspected case of typhus fever aboard the Italian steamship *Regina d'Italia*, which arrived from Genoa and Naples on August 25 has resulted in quarantining the ship. Fifty-eight cabin and 436 steerage passengers have been detained on Swinburne and Hoffman Islands for observation. The suspect is a cabin passenger, 75 years of age, who is said to have been ashore at St. Michael's, in the Azores, where the ship touched.

Gifts and Bequests.—The will of Emil Roth makes bequests of $1,000 each to Mount Sinai Hospital, St. John's Guild, the Hebrew Orphan Asylum, and the Charity Organization Society of New York.

By the will of the late Benjamin F. Hiestand, of Marietta, Pa., the sum of $1,000 is bequeathed to Columbia Hospital.

By the will of the late Emily Pratt, of Philadelphia, bequests are made as follows: Pennsylvania Hospital $5,000; Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases $5,000; Children's Hospital $5,000; Episcopal Hospital $2,000.

By the will of the late Mary Wright of Philadelphia the sum of $30,000 is bequeathed to Christ Church Hospital.

An Intensive Study of the Prophylaxis and Treatment of Venereal Diseases.—Appropriations have been made to the following institutions from the Scientific Research Fund of the Board for the purpose of discovering more effective medical measures in the prevention and treatment of venereal diseases.

1. *Leland Stanford Junior University Medical School:* "Investigation into more effective treatment in acute and chronic gonorrhea." Under the direction of Dr. R. L. Rigdon, chief G. U. Clinic, and Dr. A. S. Spaulding, professor of gynecology. "The Permeability of the meninges to antisyphilitic drugs—an attempt to increase their permeability." Under the direction of Dr. H. C. Mehrtens, professor of neurology, and Dr. Thomas Addis, director of the laboratory. "Investigation into more effective methods of treating syphilis." Under the direction of Dr. H. Alderson, associate professor of medicine.

2. *University of Michigan College of Medicine and Surgery:* "A research for an improved method of demonstrating the spirocheta pallida in human tissues." Under the direction of Dr. A. S. Warthin, director of pathological laboratory.

3. *Johns Hopkins Medical School:* "Development of new synthetic drugs for the treatment of gonorrhea." Under the direction of Dr. E. C. White, experimental chemist to Brady Urological Institute. "Manufacture and investigation of a series of new organic compounds in the treatment of syphilis." Under the direction of Dr. D. M. Davis. "Manufacture and investigation of a series of penetrating organic dyes in the treatment of chancroids." Under the direction of Dr. E. O. Swartz. "Experimental study of various methods of early treatment of venereal infection with the object of developing simpler technic, more efficient and less expensive drugs." Under the direction of Dr. William Jack.

4. *University of Wisconsin Medical School:* "An attempt to prepare mercurial and arsenical com-

pounds which have a predilection for the central nervous system, in the hope of finding drugs more useful than any known in the treatment of syphilis of the central nervous system." Under the direction of Dr. A. S. Loevenhart, director of laboratory.

5. *University of Nebraska College of Medicine:* "(*a*) Investigation relative to the development of an internal urinary antiseptic." "(*b*) Investigation of the value of certain aniline dyes in the treatment of gonorrhea." Both under the direction of E. G. Davis, M.D., director of pathological lavatory.

6. *St. Louis University College of Medicine:* "Studies in infection by gonococci." Under the direction of R. A. Kinsella, M.D., director of the department of experimental medicine.

7. *Woman's Medical College of Pennsylvania:* "A serological study of syphilis in pregnant women and new-born children, with special reference to the efficacy of the accepted methods of syphilitic treatment." Under the direction of Bertha M. Meine, M. D., director of research department.

8. *Washington University School of Medicine:* "The laboratory (biological) investigation of the latent syphilitic as a 'carrier.'" Under the direction of Martin F. Engman, M.D., professor of dermatology. "A study of hereditary transmission of syphilis." Under the direction of P. C. Jeans, M. D., instructor and associate in Pediatrics, and Jean V. Cooke, M.D., associate in pediatrics.

9. *Cornell University Medical College:* "Serological study of the gonococcus group." Under the direction of John C. Torrey, Ph.D., professor of hygiene.

10. *Jefferson Medical College of Philadelphia:* "A series of studies for the recognition and diagnosis of *Treponema pallidum* in venereal diseases, and the effect of various drugs and materials as germicidal agents against *Treponema pallidum*." Under the direction of Randle C. Rosenberger, M.D., professor of hygiene and bacteriology.

11. *Yale University Medical School:* "Effect of aniline dyes, particularly gentian violet, on the gonococcus with reference to the growth of the organism in media containing the dye, and with reference to the effect on organisms in tissue (therapeutic effect)." Under the direction of J. M. Flint, M. D., and J. W. Churchman, M.D., professors of surgery. "An intensive study of methods for the isolation and identification of the gonococcus with a view to the determination of the homogeneity or heterogeneity of strains and their etiological relationships." Under the direction of George H. Smith, M.D., assistant professor of department of pathology and bacteriology. "The demonstration of syphilitic nature of unusual lesions encountered at the post-mortem table." Under the direction of M. C. Winternitz, M.D., professor of pathology and bacteriology.

12. *Union University Medical Department, Albany:* "For studies on the nature of the Wassermann reaction." Under the direction of Thomas Ordway, M.D., dean and associate professor of medicine. "An attempt to produce generalized infection in lower animals with *Treponema pallidum* or gonococcus." Under the direction of George S. Graham, M.D., professor of pathology, and W. M. Baldwin, M.D., professor of anatomy.

13. *University of Minnesota Medical School:* "A study of the permeability of bacterial membranes, particularly in the organisms of venereal diseases." Under the direction of W. P. Larson, M.D., chief, department of bacteriology and immunology, and J. F. McClendon, Ph.D., associate professor of physiology. "Investigation of the chemical and physical properties of the cerebrospinal fluid in the luetic and nonluetic." Under the direction of L. G. Rowntree, M.D. chief department of medicine, and Charles E. Nixen, M.D., instructor in nervous and mental diseases. "Investigation of phenol alcohol derivatives in relation to their antisepsis and chemotherapy of the gonococcus and spirochete." Under the direction of A. B. Hirschfelder, M.D., chief, department of pharmacology, and H. G. Irvine, M.D., assistant professor of dermatology and syphilis.

14. *Harvard University Medical School:* "An investigation of the properties contributing to the toxicity of arsphenamine, neoarsphenamine, and analogous products." Under the direction of Reid Hunt, M.D., professor of pharmacology.

Appropriations have also been made from the same fund to the following institutions for the purpose of organizing or completing the organization within those institutions of departments of hygiene, the curricula of which shall include "courses and conferences in informational hygiene, and courses, conferences and training in the applications of hygiene, emphasizing with appropriate and due proportion and proper tact and persistency the serious importance of the venereal diseases, their causes, carriers, and prevention, and emphasizing at the same time the other important facts and applications of general hygiene, individual hygiene, group hygiene, and intergroup hygiene": Los Angeles, Cal., State Normal School; Natchitoches, La., Normal School; Maryland Normal and Industrial School (colored), Maryland State Normal School; Michigan State Normal School; Winona, Minn., Normal School; University of New Mexico; Valley City, N. D., Normal School; Reed College, Portland, Oregon; Bellingham, Wash., Normal School; University of Utah, Alcorn; Miss., A. & M. College (colored); Woman's Medical College of Pennsylvania; Harvard University; University of Missouri; Colorado State Teachers' College; New York State Teachers' College; Cornell University; University of South Carolina; Northwestern University; University of Pennsylvania; Cheney, Wash., State Normal School; Milwaukee, Wis., Normal School; Indiana University, Bloomington, Ind., University of North Carolina.

A further appropriation was made to a committee of psychologists under Dr. J. R. Watson of Johns Hopkins for "the purpose of investigating the informational and educative effect upon the public of certain motion picture films used in various campaigns for the control, repression, and elimination of venereal disease."

Obituary Notes.—Dr. Paul N. Markley, formerly of Hataboro, Pa., died at his home in Camden, N. J., on August 18, aged 58 years. He was a graduate of the University of Pennsylvania, in 1882. At the time of his death he was superintendent of the Sunny Rest Sanitarium at Ancora, and was on the staff of the Glen Garden Institute.

Dr. SAMUEL TRIMBLE died at his home in Lima, Delaware County, Pa., on Aug. 6, at the age of 73 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1867.

Dr. JOHN RUSSELL DICKSON died at Gettysburg, August 28, at the age of 90 years. He was graduated from the medical department of the University of Pennsylvania, in the class of 1880. He was a member of the Adams County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. SAMUEL L. REA died at Oxford, Pa., on August 17, at the age of 76 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1871.

Dr. JESSE WILLIAMSON of Chestnut Hill, Philadelphia, died at Bay Head, N. J., on August 18, at the age of 66 years. He was graduated from Jefferson Medical College in the class of 1873. He was a member of the Medical Society of Delaware.

Correspondence.

COMPULSORY HEALTH INSURANCE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The medical profession of this State will have to meet the menace of compulsory health insurance this year by an entirely different course of procedure to what has been pursued in the past.

The timely warning given at the last session of the Legislature of the danger of the passage of this bill, owing to its advocacy by the Governor, aroused the opposition of every county medical society in the State and resulted in its unanimous condemnation by the entire medical profession of New York.

This opposition found expression in the largest and most representative delegation of the profession which ever appeared before the Legislature in opposition to a measure unfavorably affecting the practice of medicine.

Despite this fact, certain influences have been at work since then in the State Society to neutralize this opposition to a measure which would place the practice of medicine, so far as it relates to 80 per cent. of the population of this State, under the control of the State Industrial Commission, a political body dominated by the State Federation of Labor.

At this writing the Erie County Medical Society has announced a symposium on compulsory health insurance, and has invited to its discussion Senator Davenport, the author of the Davenport bill; James M. Lynch, State Industrial Commissioner, and other public servants, who, while drawing pay from the State, are endeavoring to destroy the practice of medicine as a private avocation, and transform it into a public function like the State police and the State Department of Health.

At the convention just held of the State Federation of Labor compulsory health insurance was urged for adoption by Governor Smith, who likened our neglect of health to the neglect of our forests, upon the conservation of which we are now spending millions. With all due respect, this is "old stuff," like the complaint that we were spending millions upon the care of our hogs and nothing upon the care of our children, the best answer to which was that when children and hogs were brought up alike in the country it would then be proper for the Government to equalize its expenditures upon both. James M. Lynch declared that compulsory health insurance was a matter of "social welfare" and not a matter of "partisan politics." Such being the case, it behooves every member of the medical profession to obtain from the candidate for the Legislature in his district an expression of his attitude on this question before his support is given to him at the polls. A united medical profession appearing at Albany commands no respect under existing political conditions from the elected member of the Legislature. The State Society has arranged to discuss this matter after election in a committee appointed by its president. The make-up of this committee gives no promise of its being opposed to compulsory health insurance. The only hope of successfully combating compulsory health insurance in the next Legislature is from a discussion of this subject with the candidates for this body before election by the individual doctor, his wife, his druggist, his dentist, his patients, and his friends.

JOHN P. DAVIN, M.D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 7, 1919.

Orthopedic Hospitals in Great Britain.—Owing to the conditions created by the war the practice of orthopedics, of course, has vastly increased in Great Britain. Reconstruction and restoration of human material has necessarily gone on apace, and, thanks largely to Sir Robert Jones of Liverpool, the facilities afforded for the repairing of those maimed and disabled are not excelled in any other country. Not only is there a chain of hospitals specially devoted to orthopedic treatment from one end of Great Britain to the other, but almost every hospital of any size has an orthopedic department. The Norfolk and Norwich Hospital, one of the best built and equipped of the provincial institutions, is now asking for the sum of $150,000 to erect and furnish an orthopedic department. The Norfolk and Norwich Hospital, situated in the heart of Norwich, one of the oldest and most renowned cities of England, has done excellent work during the war and really requires a special orthopedic department. It may be said that the Eastern Counties of England directly felt the effects of war more than any other part of England and were made a center for vast military camps. It may be mentioned also that the Eastern Counties have always been famed for their surgeons and physicians. Sir James Paget and his brother, Sir George Paget, were Norfolk men. Cadge was a Norwich man. Holden, the anatomist, lived in Suffolk; Sir William Gull was a Suffolk man. Indeed, the list of Eastern Counties men who have risen to eminence in the medical profession is a very long one. It should not be forgotten that Sir Thomas Browne lived and died in Norwich. This ancient city still upholds its high traditions, and Norwich is celebrated at the present time as a medical center.

Post Graduate Teaching in London.—While the resources of London, so far as material is concerned,

are unrivaled in any city of the world, the opportunities provided for post-graduate instruction have been, and it may be said, still are, almost beneath contempt. Since the German débâcle and since it has appeared more or less evident that the German schools of medicine will not be frequented for the purpose of post-graduate medical instruction as they were before the war, efforts have been made for placing London in her rightful position as a great post-graduate center. A scheme for rendering London the place in Europe to which foreigners and especially Americans may come with the assurance that they will find therein a well-organized system of post-graduate medical teaching has been under consideration and discussion for a period of something like two years. It has been stated that the plans in this direction are advanced and the foundation of the American Hospital in London seems to show that progress has been made. And yet, considering the objects at stake, the question is, has progress been rapid enough? Has a system of organization and unification of the hospitals been evolved and are efforts being made to bring these into effect as soon as possible? The fear has been expressed recently that unless the medical profession of London actively bestirs itself New York will forestall her, and that the metropolis of the New World will become the seat of the greatest medical teaching schools of the world. The causes for this fear are the news that steps have been taken to raise the sum of $50,000,000 for this purpose. As a matter of fact, there is room and plenty of room for London and New York as centers of post-graduate medical teaching. Further, with regard to America and Great Britain, it will be to the best interests of both if their medical men and medical students exchange visits for the purpose of post-graduate medical instruction. London should be the medical center of Europe and New York that of the Americas.

The London Water Supply.—Sir Alexander Houston, director of Water Examination, London Water Board, was the introducer of chlorination of water, a method which has been of the greatest benefit to health, and which was largely responsible for low mortality and morbidity rates among the British armies during the war. It is not too much to say that the device for purifying water by chlorination is one of the triumphs of preventive medicine. In his thirteenth annual report, Sir Alexander Houston states that the bacteriological results of chlorination are better in winter than in summer and that chlorination on the average succeeds considerably better than storage. It is practically three times superior during the winter months, when both the river water and the stored water give the least satisfactory results. Houston says that, despite the magnitude of the treatment, 70 to 80 million gallons of London water being treated by chlorination daily, no complaints have been received as regards taste since the method was first started in June, 1916.

Treatment of the Tuberculous in London.—An agreement has been come to between the Public Health Committee of the London County Council and the Insurance Committee with respect to residential treatment of insured tuberculous individuals. At the present time the Council finds a certain number of beds for such persons in sanatoriums and hospitals. By the new arrangement a far larger number of beds will be provided, to which the Insurance Committee will have the right of nomination. The number available for insured persons who are recommended by the Insurance Committee for indoor treatment is to be, at least one hundred more than the funds of the Insurance Committee might, according to the estimate of the Minister of Health, be expected to provide. It has also been arranged that the Council and the Insurance Committee shall each appoint three representatives to confer on any general question of administration, and disputes are to be referred to the Ministry of Health. The Council has likewise entered into an agreement whereby it becomes responsible for the indoor treatment of discharged soldiers and sailors. The cost of this is to be borne by insurance and exchequer funds. The Council now funds 200 beds for adult cases of tuberculosis, and, according to the agreements just entered into, it must provide at least 860 additional beds. The Council has thus become the central administrative body for dealing with residential treatment for all tuberculous persons who require such treatment through local authorities in London.

8. The Necessity for Early Amputation.—Henri Brachet in this paper refers only to the wounded who must be treated at the nearest ambulance before being sent to the rear. He classifies the wounded coming to the ambulance under the following three distinct clinical headings, taking into account above all the general condition—shock and infection: (1) Crushing or avulsion of the limb without shock or infection; (2) crushing or avulsion of limbs with shock or infection; (3) crushing or avulsion of limbs with shock and infection, or early infection only. Amputations done at the first line ambulance are usualy clearly indicated; the time and the procedure are the two points to be considered. Usually the case will not allow of conservative treatment; the mutilation or the destruction of tissue is such that no hesitation is possible. If the surgeon is sufficiently conservative and if doubtful cases are sent to the rear after receiving proper treatment, such as the removal of bone splinters and thorough disinfection of the wound, the indication in the remaining cases is perfectly distinct. With surgeons who have had experience in war surgery the balance will probably be in favor of operation if the lower limb is the seat of injury, while conservative treatment will be adopted in the case of an upper limb. Aside from this formula the surgeon must be left to his own judgment as to the cases requiring amputation for the lesions per se and those in which infection appears during the days following. While interventionists may sometimes have to regret the hypothetical preservation of a limb or one of its segments, conservatives often have to regret the loss of life. The indications for amputation are distinct, even if the destruction of bone is not considerable, where there are extensive injuries to arteries, nerves,

and muscles. On the other hand, if comminuted fractures exist, with integrity of the vasculonervous bundle, conservative treatment may be essayed. Severe infection or necrosis may force amputation as the only solution even if the bones are intact or little damaged. Theoretically, the subject should be operated upon as rapidly as possible in order to remove the traumatic focus which is the source of early infection. In practice this reasoning does not apply and it is here that the three classes of cases referred to must be taken into account. The first class (without shock or infection) offers no contraindications to immediate amputation or other interference. In the second class (patients with shock) operation must not be resorted to. This rule must never be laid aside. In a patient with shock the addition of operative shock is to be avoided. These patients must be put in a heated bed, given hot drinks, and the pain eased by small repeated doses (one centigram) of morphine. A valuable stimulant is a hot enema composed of 300 c.c. salt solution to which is added a little infusion of coffee or rum. The salt solution as well as caffeine and camphorated oil may be given subcutaneously. Hot water bottles, heated bricks and other mechanical means of warming the patient, and above all, rest in bed are of vital importance. In the majority of patients, with this treatment and four or five hours' rest, the blood pressure assumes a better tone. As soon as this amelioration is noted operation should be done at once. The lamentable statistics of the early days of the war are the partial result of ignorance of this rule. When a patient offers both shock and infection, the former condition must be watched in order to be able to conclude that there is also infection. The latter is shown by an evening temperature probably around 97° F. and the following morning a temperature of 102.5° to 104° F., with rapid pulse. Sometimes infection is superimposed on shock. When infection has once developed nothing is gained by waiting. Immediate operation is the only hope and the surgeon need not regret a too hasty interference. If there is a massive gangrene with a typically ascending progression, the writer's advice is to amputate. If the case is one of ordinary partial gangrene, the parts are merely to be exercised, but the patient must be seen again in five or six hours, because such conservative interference may be insufficient. Gas gangrene is an indication for urgent intervention, but is infrequent at a first line ambulance. If septicemia exists with a large infectious focus in which other infections may develop, one should amputate. But if the patient has a well drained fracture he may be treated conservatively, for it is more than probable that he has quite as much chance to pull through without amputation.

3. A New Operation for Duodenal and Gastric Ulcer.—J. Shelton Horsley reviews the various operations most generally employed, shows why they frequently fail, and presents a new operative procedure in which he applies the well-known surgical principles that have been established for the treatment of fissure in ano (which presents a condition analogous to that found in gastric and duodenal ulcer) namely, temporary paralysis of the sphincter and excision or cauterization of the ulcer. The operation consists in exposing the upper portion of the duodenum and the pyloric end of the stomach through an ample abdominal incision. A point is selected in the midline of the anterior surface of the duodenum an inch from the pylorus, and another point on the stomach not less than two inches from the pylorus and midway between the greater and lesser curvatures. Each of these points is grasped with an Allis forceps or fixed with a suture. The stomach and duodenum are then surrounded with moist gauze. An incision is then made from the point on the duodenum to the point on the stomach. If the ulcer is in the anterior surface of the duodenum, the incision should pass along the lower edge of the ulcer. An effort is made to divide the peritoneal and muscular coats without opening the mucosa. The incision should go no further than one inch into the duodenum. It extends two or more inches into the stomach. The mucosa is incised, care being taken to include as little of the mucosa in the grasp of the forceps as possible. If the ulcer is along the incision, it is excised from the mucous surface, and the forceps, scissors, and knife used in the incision are laid aside, as they are probably septic. If the ulcer is in the posterior wall of the duodenum or pylorus the wound is retracted, the ulcer exposed and excised. The deeper structures are sutured with tanned or chromic catgut, and the mucosa is gently approximated with a continuous suture. The suture in the mucosa must not be tight. If there is an old contraction resulting in pockets, the mucosa and the contracting band should be divided and the mucosa sutured transversely to the incision. To avoid hemorrhage, the incision that relieves the contracting band should be short and should divide only the superficial part of the band. Neglect of this precaution resulted in a fatal secondary hemorrhage in one case. A second suture placed half way between this middle suture and the upper angle of the wound renders suturing the upper half of the incision easier. A No. 1 tanned or chromic catgut suture is then started at the lowest portion of the wound, which is in the stomach wall. The suture is tied at the upper portion of the wound and the ends left long and clamped. A second row of sutures takes in the muscular coat. A third row of sutures of fine tanned or chromic catgut is placed after the gauze around the stomach and duodenum has been removed. This row includes the peritoneum and muscular coats, and buries the first and second row of sutures completely. This is a continuous mattress suture. A portion of the gastrocolic omentum or else the right edge of the great omentum can be brought up over the line of incision without tension. It is fastened with interrupted stitches of fine catgut. If the ulcer is not in the duodenum or the pyloric region, the operation, as described, may be done in order to relieve the spasm of the pylorus and the ulcer then excised or cauterized, as advocated by Balfour, through another gastric incision. The advantages of this operation are that it removes the obstruction and the pathological condition and it permits the normal resumption of the stomach function. The ends of the sutured incision are within the stomach wall and the scar tissue that may remain about the pylorus is approximated, not with other scar tissue, but to healthy stomach wall. There is no pouch formation as on the Heineke-Mikulicz operation, in which the center of the incision is at the pylorus. The parts put at rest are the parts most concerned in the contraction and relaxation. The function of the pylorus and pyloric end of the stomach is not permanently destroyed. The operation is simpler than the Finney operation. Dr. Horsley has operated on eleven patients by this method, two of whom died. Of this number three patients had gastric ulcers with one death, which could hardly justly be attributed to the pyloroplasty, one was complaint free, and one had a recurrence which required a second operation from which the patient was recovering. There were two patients with pyloric stenosis, one being complaint free and the other dying from secondary hemorrhage. There were six patients with duodenal ulcer, in whom the ulcer was probably not the chief pathological condition, who were greatly improved, and four, in whom the ulcer was evidently the chief lesion, who were complaint free.

1. An Address on X-ray Therapy.—Robert Knox, in this address delivered before the Hampstead Medical Society, gives a summary of *x*-ray therapeutics and describes the technique for a number of diseases which benefit from radiation treatment. He reviews the far-reaching effects of the discovery of *x*-rays and the subsequent isolation of radium in the field of physics and crystallography. These discoveries have revolutionized our conception of the atom. In commenting on the achievements and possibilities of the *x*-rays in relation to medicine, he says that the *x*-ray skillfully used can influence practically all the tissues which go to make up the living organism, the degree of action depending solely upon the quantity of radiation used and the response to it of the tissue affected. Obviously the action must be a general one, whose activities are at present only vaguely understood. So far we know that definite results follow upon definite doses of radiations, and if this fact is grasped we go a long way toward a comprehension of the governing principle of radiation therapeutics. The future teaching in the medical sciences with relation to radiation must take more cognizance of physics. Medical education may be revolutionized in this way. A thorough appreciation of the action of radiations on normal tissues will be valuable when we come to deal with morbid conditions. What is now known of the effects of radiation on the living cell is, broadly speaking, that if a particular cell or group of cells be exposed to a beam of radiations from any source certain events may follow: (a) The cell may be stimulated; (b) its activities may be inhibited; (c) the cell may be destroyed. The determining factor in any of these ends so far as the radiations are concerned, is the intensity of the radiation and the duration of the exposure. In regard to the cell the determining factor will be the resistance the cell possesses to external stimuli. This is in fact the most difficult problem one encounters in determining dosage. These facts indicate that treatment by radiations must of necessity be solely in the hands of experts whose training will enable them to obtain the maximum of good and the minimum of harm in the treatment of diseased conditions. The changes induced in cellular structures may be termed the *direct effects* of radiation. There are, however, *indirect effects* produced which may have a far-reaching influence upon the metabolism of the organism. If a dose of *x*-rays is excessive, cell activity is arrested and the cellular structures die. The destroyed cells are absorbed or rendered inert by the activity of the surrounding tissues. When absorption takes place the products of disintegration are carried by the lymphatics to other organs of the body and far-reaching effects may follow. The products of disintegrating cells may be circulated in the blood and serum and produce beneficial or harmful effects. If the former the tissues are toned up and the patient improves; if the latter the patient may be reduced to an extreme degree. This is especially liable to occur in the treatment of diseases of the blood, such as leucemia, where, if care is not exercised, a rapid fall of the white cells may lead to a fatal leucopenia. A description of the technique and a summary of the value of radiations in their application to particular diseases is given. Diseases of the skin, such as ringworm, rodent ulcer, malignant disease of the skin, and hyperidrosis are particularly responsive to regulated doses of *x*-ray. The growing experience in the treatment of enlarged lymphatic glands is forcing upon us the conviction that in the *x*-ray we possess a remedy of great power, and one that is also of diagnostic value since it has been found that enlarged glands respond in somewhat the following manner to estimated doses of radiations: Simple inflammatory conditions give a rapid response. Lymphadenomatous glands give a fairly rapid response. Sarcomatous and lymphosarcomatous glands give a rapid response in the majority of cases treated, but the effect is rarely permanent. Tuberculous glands give a slow response, as a rule, while carcinomatous glands give a very slow response and hardly ever completely disappear. Enlarged glands due to a mixed infection quickly subside under radiation. All, or nearly all, may disappear, or one or more of a group of enlarged glands may persist. These may ultimately be found to have invading cancer cells in their substance. In the *x*-ray treatment of exophthalmic goitre, three areas of the thyroid gland should be irradiated, one on the right side, another on the left, and a central large area including the isthmus of the gland and the thoracic region, the object being to include the thymus gland. Evidence shows that a number of diseases of the blood and ductless glands respond favorably to radiation. The technique for the treatment of fibromyoma of the uterus and other conditions of the pelvic organs is gone into in detail. The aim of the treatment in these conditions is to produce the result gradually. The immediate and later reactions to radiation should be known to the practitioner so that he is in a position to advise his patients on these and other points arising in the course of treatment. Of the immediate effects nausea is the most common, and is probably due to the inhalation of highly ionized air which is found in the vicinity of all high tension electrical machinery. Headache and giddiness may also occur. The later effects come on several days after the treatment and appear to have a direct relationship to the intensity of the dose. In cases in which the dosage has been very heavy, there may be intense prostration, rapid pulse, raised temperature, and feelings of malaise. The treatment consists of rest in bed and careful attention to diet. The patient usually recovers in time for the next series of treatments. Put briefly, the advantages the *x*-ray treatment possesses over other forms of treatment are that it is quite painless, and if it fails operative procedures may be employed under the same conditions as before or even under improved conditions. It is not accompanied by so much risk as the operative, and the after effects are not so disturbing or so lasting. In speaking of the treatment of malignant disease by radiation, the writer states that the final judgment is in favor of operation in all early cases of cancer, and delay is always dangerous, since it is not yet possible to be certain that radiations will invariably yield a successful result and surgery may ultimately have to be employed under less favorable conditions.

2. On Abdominal Thoracic Wounds of Warfare.—Gordon Taylor relates his first experience in assisting Sir John Bland Sutton perform an urgent thoracolaparotomy in 1910 or 1911. The thorax was opened by a vertical incision dividing the lower costal cartilages, and the abdomen was subsequently opened in the left linea semilunaris by a prolongation downward of the thoracic incision. This incision for dealing with abdominothoracic wounds was the prototype of the thoracolaparotomy reintroduced by Pierre Duval in 1917—some six years later. The writer states that all statistics go to show that the immediate prognosis of an abdominothoracic wound is in many cases largely determined by the nature of the abdominal injury. Those that are accompanied by a wound of a hollow viscus are very fatal. Thus Sir Cuthbert Wallace found that only 7 out of 28 such cases were evacuated to the base—that is a mortality of 75 per cent. Gask and

Wilson in one series of 13 cases saved only three, and another series showed only one recovery in five. Lockwood managed to save eight out of 20, while the writer has records of 11 recoveries out of 22 cases, a recovery rate of 50 per cent. His own personal series of 75 abdominothoracic cases submitted to operation, or at least transfused with blood with a view to operation, represents practically every abdominothoracic case admitted to his casualty clearing station from the end of the Cambrai campaign, in 1917, to August, 1918, and several cases operated on during the early part of the autumn advance. The cases complicated by hollow viscus injury gave a recovery rate of 50 per cent. Those complicated by wound of a solid viscus showed a recovery rate of 70 per cent. An analysis of 27 cases that ended fatally shows that two died before any operation could be performed, 13 in less than twelve hours, and one in eighteen hours, presumably from abdominal injury. The remaining 11 all died of some form of chest complication—massive collapse, pneumonia, thoracic sepsis; one died of subphrenic abscess. The writer has also collected the records of 207 cases of abdominothoracic injury operated on by himself or some of his colleagues in the Fourth Army. Of these cases 138, or 66.6 per cent., made a good recovery. These results when compared with the figures given by Sir Anthony Bowlby at the Surgical Congress at Val-de-Grace in November, 1917, namely, 151 cases with a recovery rate of 49 per cent., show a remarkable improvement. Sir Cuthbert Wallace, in the summer of 1918, reported a series of 70 cases with a recovery rate of 44.3 per cent. The writer considers it remarkable that so few cases of diaphragmatic hernia have been recorded and thinks that perhaps Lockwood's contention that very few of these cases survive is true. He thinks that the thoracic route is the right method of approach for dealing with a diaphragmatic hernia, and states that in the treatment of abdominothoracic injuries, just as in those of other regions of the body, the successive years of the war have witnessed a steady progress.

1. Men of Medical Training in Congress.—William Browning says that in reply to the query "Shall the physician go into politics?" two opposite notes are heard, a major one of high advice that they shall keep out and devote themselves wholly to the immediate needs of their calling, and an occasional minor wail at the lack of our representatives in official and especially legislative circles. This question, he believes, can be approached more intelligently if we are familiar with what has been, and to this end he has consulted the 1911 edition of the "Biographical Congressional Directory." He has from this source compiled a complete list of medical representatives, delegates, and senators in Congress from 1789 to 1910, inclusive. He finds during this period a total of 274. Not all of these started professional life at a period when medical degrees were customary. All of those listed studied medicine, however, a few switching to other lines before finishing. Most of them had some experience in practice and most of them kept it up. The largest number of waywards, fifty in all, took up law. In addition to those listed there were a number of medical men elected who did not serve. An inspection of the list shows the names of several men with a high record for statesmanship. Others can be recalled as individuals of distinction in their time and region, or as political leaders, or just clever politicians. But few of these men appear to have been greatly distinguished in medicine or science of any kind. They might be expected to take an active part in advancing science, medicine, and public health, which has been true in some cases. In seeking to answer the question whether any particular part of the country produces and utilizes more medical congressmen than other parts, the writer has tabulated the number of medical congressmen coming from each State. This table shows that the States furnishing the largest number are Pennsylvania, New York, and New Jersey, the number being respectively 39, 32, and 23. In proportion to respective areas New Jersey has elected the most, while Connecticut has produced the most. These men seem to have been chosen predominantly from the country districts. A study of the number serving each year during the period under consideration shows that this number varies with little apparent reason, from a minimum of one in 1864 to a maximum of sixteen in 1821, and again in 1855 and 1856. The writer has been unable to ascertain to what extent the activities of these men jibe with our public interests, and he is likewise unable to answer the question whether such men lose their "medical conscience" as soon as they are in politics. He believes, however, that they can be of special use to the community as representatives of increasing scientific and allied needs.

Correspondenz-Blatt für Schweizer Aerzte.

May 31, 1919

Etiology of Influenza.—Burckhardt takes up this subject with energy and makes the problem revolve about Pfeiffer's bacillus. In other words, are the two great pandemics due to one and the same cause? The early epidemic was found to be due in every case examined by Pfeiffer himself to the bacillus which bears his name. It is true that the latter made his studies on the aftermath of the epidemic in 1891-2, which fact might come to count for a good deal. However, smears had been kept of sputum from the earliest cases and the germ was equally present in that connection. He also conveyed the disease to animals. The case seemed to have been proven throughout. But as the pandemic wore away the nature of the finds underwent some alteration. The Pfeiffer germ was discovered in various other affections, while in endemic influenza other organisms were found even to the complete exclusion of Pfeiffer's. A so-called pseudoinfluenza bacillus described by Pfeiffer as present in pseudoinfluenza was no longer recognized, at least by that name. When the present pandemic began, the bacteriologists included not a few who found the Pfeiffer germ in evidence, but never in pure culture and not by any means in every case examined. As time went on a few men announced a high percentage of Pfeiffer cases. But many good men reported an almost complete absence of Pfeiffer cases. The author has never in a series of 90 cases found a single one with this causation. He next devised a more radical technique which he tested on influenza cases and normal controls and found the bacillus present to the same extent in both series. The percentage was around 20. One may now recall that the controls also showed the same behavior in the first pandemic. When the Pfeiffer germ is not found, what replaces it? Various cocci, mostly diplococci. The strains of the germs in question are very difficult to isolate and characterize. We do not know if they are in any way specific for the disease. In some cases, moreover, the sputum is quite sterile. A grippe streptococcus was described in 1911.

Strychnine Poisoning and Tetanus.—Studies by Lhermitte appear to show that these two affections may be more nearly allied than is generally believed. In a recovered case of strychnine poisoning he obtained information which showed that for 15 days after recovery there was a peculiar status not unlike tetanus with major convulsions left out. In this postconvulsive stage he saw an extreme excitability of the reflexes of the tendons with foot clonus. The socalled defensive reflexes were also extremely active and there was hyperexcitability to both electric currents. These analogies with tetanus allow us to believe that the pathogeny of the two affections may be identical and due to an intoxication of the posterior portion of the cord.—*Gazette des hôpitaux.*

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-fourth Annual Meeting, Held at Atlantic City, N. J., June 16 to 18, 1919.

(Special Report to the MEDICAL RECORD.)

First Day—Monday, June 16.

DR. A. MCPHEDRAN OF TORONTO, CANADA, IN THE CHAIR.

Presidential Address.—Dr. MCPHEDRAN, in his address, thanked the members for the honor they had bestowed upon him in electing him, a Canadian, to be president of the Association. He expressed the hope that the cordial relations between the United States and Canada, strengthened by their being allies in the war, might continue. Dr. McPhedran spoke about the development of medicine during the war, and hoped that the lessons learned and the experience gained would be applied to the advantage of the civilian population.

Election of Officers.—This resulted as follows: *President*, Dr. Hermann M. Biggs, New York; *Vice-President*, Dr. William S. Thayer, Baltimore; *Secretary*, Dr. Thomas McCrae, Philadelphia; *Recorder*, Dr. T. R. Boggs, Baltimore; *Treasurer*, Dr. Joseph A. Capps, Chicago; *Councillor*, Dr. Lewis A. Conner, New York.

Elements of a Pragmatic Psychiatry.—Dr. E. E. SOUTHARD of Boston presented this topic. He stated that pragmatism was developed in America in 1895 by William James. Christian Science and osteopathy were practical, but not pragmatical. The test of pragmatism was measured, not necessarily by the success of an undertaking but by the benefits which resulted from its development to the individual and to society. Mental disorders fell into a grouping of ten classes: (1) Syphilis; (2) feeble-mindedness; (3) epilepsy; (4) alcoholism; (5) focal brain; (6) somatic (as typhoid states); (7) senile; (8) dementia precox; (9) manic depressive states; (10) unknown.

Psychology: A Plea and a Prophecy.—Dr. JOSEPH COLLINS of New York presented this topic. He said that medicine, as revealed by the war, was found lacking more in the field of neurology than in any other field. Physicians were found incompetent to examine, interpret, and treat disorders of the nervous system. The medical profession here was not now prepared to do the work of reconstruction as well as the medical profession of other countries. The branch of medicine known as neurology had not been adequately taught to medical students in this country. The branch of medicine known as psychology had been treated by pedagogists with scorn. Alleged psychologists had not seen the necessity of being physicians first and psychiatrists second. During the war the experience at cantonments showed that many officers and soldiers were not fitted to be in the army. Up to 3 per cent. of men in training were the subjects of nervous disease. The speaker said he had eliminated seventeen men in one day for functional and nervous disturbances. France had had schools of medicine in which neurology was well represented, and they, the French, had worked out the question of pensions well. In England it was the reverse. England had 25,000 men on her pension roll incapacitated by neuropsychoses. Eventually admissions to college would be determined by psychological tests and not by the knowledge the applicant might possess. The choice of a profession would be determined by psychological examination. Men fitted for the ministry, for example, would not go into medicine, and vice versa. Civil service examinations would be conducted along psychological lines. In pedagogy, children would be classified into groups by psychological tests, and promotions would depend on them. Potential psychoneurotics would then be recognized before incapacitating symptoms arose. Feeble-mindedness would be detected. Drunkards, hoboes, and prostitutes would be recognized and eliminated. Medicine was going to be improved by team work along this line. Already the business man was utilizing psychology in choosing his employees. Psychology should be hailed with the enthusiasm with which chemistry was hailed years ago. Psychiatry should be taught in medical schools as abnormal physiology. Before it could be taught three things were needed: (1) Schools or hospitals; (2) teachers; (3) the proper atmosphere.

Dr. R. C. CABOT of Boston said that at Harvard they had formed a committee on the correlation of studies, to which the professors and instructors belonged. The aim of the committee was in part to get the ideas and points of view of the students, as well as to map out the curriculum of the school. With relation to Dr. Southard's classification, it seemed to him that one should establish such a list for differential diagnoses to serve as a basis to include or exclude all diseases. He had arranged such a list under ten headings: (1) Infectious; (2) Exophysical; (3) Neoplastic; (4) Toxic; (5) Metabolic; (6) Endocrinal; (7) Anaphylactic; (8) Psychoneurotic; (9) Congenital or agenetic; (10) Unknown. Such a list would apply equally well to all diseases—of the eye, of the heart, and so on. Those who had studied nomenclature in the classification of diseases had wavered between two problems—etiology and region. If one had such a list as this applied to each organ, one would not give up the advantage of knowing about the organ, and yet one would have the order to approach the disease from the standpoint of etiology and regional diagnosis.

Dr. E. P. GAY of Berkeley, Cal., said Dr. Southard had been forced to a nosology based on effects. Others had been forced to a nosogoly based on diagnosis, but the two methods did not vary greatly.

Dr. E. E. MAYER of Pittsburgh said that if one created a science in terms of facts and factors which one wanted to study for their origin and their effects, he thought one was on safe and practical grounds. The great difficulty that psychiatry had labored under was that the profession had been under a rule of nosology that assumed that each case must be pigeonholed under one term. The trouble with Dr. Southard's classification was that each patient had to be labeled by one term. With regard to the question of inclusion of psychology, he thought that they were getting to a point where they should not be mind-shy. When one talked about mind, one talked about a simple classification of function; and one did not have to throw up one's hands. The great question was how did those who determined the policies of medical research workers in this country stand? He did not know of any of the great foundations in this country that gave aid to workers to get this on a simple, sound, practical basis. The great difficulty was that there was a great deal of mind-shyness, because mind was under suspicion. The facts that patients brought should be studied and, whatever they were, psychology or something else, they should stand on their own ground.

Dr. E. E. SOUTHARD, in closing, said that he had known of a case of an old man who was feeble-minded, was alcoholic, had focal brain disease and manic depressive insanity, and whether he was schizophrenic also was a question. One could go through the entire list. If one found a man was alcoholic and had epilepsy, which was it? One had to ask the pragmatic question, "Where did one want to put this patient?" Everybody knew that there was a group of 5 per cent. about which one could not be certain until autopsy. In regard to Dr. Gay's remark, it was true that one could harmonize cause and effect, and it was true that the cause was equal to the effect. Still effect was more than cause. The thing to do was to have one's vision on the future; that was the principle of pragmatism.

Epidemic Encephalitis.—Dr. LEWELLYS F. BARKER of Baltimore presented this paper, which included a report on ten personal observations of this disease, with six case reports in full. Emphasis was laid upon the disseminated character of the lesions in the central nervous system with predominant localization in the diencephalon, mesencephalon, and pons, though the cerebrum and spinal cord were frequently also involved. Lumbar puncture was cited as a very valuable aid in diagnosis, revealing in many cases a slightly increased cell count of small mononuclear elements, positive globulin reaction, and negative Wassermann. Many of the cases were very mild and doubtless a great many had been overlooked. The designation encephalitis lethargica was not a good one. Encephalitis nonpurulenta epidemica was a better name. The disease was not a new one, epidemics of the same sort having been reported repeatedly in earlier years. During the past

three years epidemics had occurred in Austria, in Australia, in France, in England, and in the United States. The disease was closely related to poliomyelitis, on the one hand, and to influenza on the other.

Dr. Emanuel Libman of New York drew attention to some work that had been done by Drs. I. Strauss and L. Loewe at the Mount Sinai Hospital. Working with the filtrate of the nasopharyngeal mucosa of patients suffering from encephalitis lethargica, they were able to reproduce the disease in monkeys and rabbits.

Dr. Joseph Collins of New York said it was interesting to know that the sequelæ of some of these cases of encephalitis had not so far been recorded. At the Neurological Institute they had seen five cases of what might be called generalized tic, and dystonia. Some took the form of torticollis and general dystonia throughout the entire body. He did not find himself in agreement with one statement of Dr. Barker's, and that was that there was pleocytosis in the spinal fluid. His experience led him to think that where there was excess of cells in the spinal fluid one was dealing with a meningitis predominating. The cerebrospinal fluid would point the differential diagnosis between cases of meningitis, and parenchymatous involvement. The prognosis in the two was entirely different. The encephalitis cases would get well, but the meningitis cases would not—just the reverse of what one would naturally suppose.

Dr. Frank Billings of Chicago said he wished to verify what Dr. Barker said, that the disease existed in the epidemic of influenza of 1889-1890. Cases occurred during the convalescence from influenza. The worst ones were characterized by delirium and even comatose conditions, but all the cases seen personally by him recovered.

Dr. A. Fussel of Philadelphia said that Dr. Barker did not speak of the symptom of retention of urine, which was naturally the symptom which first called the attention of the patient to the fact that he was sick. In one of the particular cases there was a small number of cells in the spinal fluid.

Dr. Barker, in closing, said that Dr. Libman's work might lead to the discovery of the cause of the disease and of the virus. The latter had been isolated as a diplococcus, but nothing seemed settled. Dr. Collins spoke of the sequelæ; Dr. Thomas had shown remarkable sequelæ like chorea electrica. He thought they would see more of these sequelæ later on, not knowing perhaps that they were sequelæ, and he felt that one might see some epilepsy. He thought it was the experience of most observers that there was an increase in the cell count in the spinal fluid. Eight of his ten cases showed that. There might be a meningeal factor, but that seemed to be so small that it was better to leave it out. Dr. Fussel had spoken of retention of urine as a primary symptom. He had not met with it, though incontinence had been reported in the literature, as a symptom. Many of the cases would be diagnosed by retrospective diagnoses. He thought that many instances of the disease were overlooked in this country.

The Diagnosis of Late Syphilis of the Central Nervous System.—Dr. Channing Frothingham of Boston, Mass., read this paper. He said that as a result of the increased use of the Wassermann blood serum test for syphilis, a considerable number of cases of syphilis were being diagnosed in which the original infection occurred some years before. In these cases of old syphilis in which the serum had shown a positive Wassermann reaction it was assumed that there were still some living spirochetes somewhere in the body, and that an attempt should be made to kill them off. It was now generally recognized that late syphilis of the central nervous system needed special treatment and this treatment should be started early. It was, therefore, important to find out where the living spirochetes were in these old cases, in order to institute proper treatment. The question arose as to whether a careful history and physical examination would reveal spirochetal activity in the central nervous system, or should that special diagnostic aid, the lumbar puncture, be resorted to. Although a lumbar puncture was not a dangerous procedure, it was often an inconvenience to the patient as it might force him to remain in bed for several days. Since the opening of the Peter Bent Brigham Hospital considerable attention had been paid to the diagnosis and treatment of syphilis of the central nervous system. As a result, lumbar puncture had been performed on practically all cases in which even a suspicion of syphilis of the central nervous system was present. It was thought that a study of these cases, therefore, might reveal some in which there were practically no signs or symptoms referable to the central nervous system and yet the spinal fluid examination would indicate syphilis. Two hundred and thirty cases were studied. The hospital diagnoses were used and the cases grouped as tabes, general paresis, syphilis of the meninges, and cerebrospinal syphilis. The history and physical examination, as recorded by the house officer on admission, were used. It was felt that this represented as good an examination as the average patient would receive in a general hospital or an out-patient department. In each group, except that of syphilitic meningitis, there was a definite small percentage of cases, between 2 and 5 per cent., in which neither the history nor physical examination called the attention of the examiner to the central nervous system, even after syphilis was known to be present. These cases would have been missed as cases of syphilis of the central nervous system if, for one reason or another, the lumbar puncture had not been performed. If this number were missed in the cases studied carefully in the wards, the opportunity would occur oftener for overlooking cases in the outdoor departments, where examinations would be made under more trying conditions. Therefore, since lumbar puncture was not dangerous, and since it might reveal syphilis of the central nervous system in which physical examination had failed to do so, and since a definite diagnosis was desirable early in order to institute appropriate treatment, it seemed fair to demand a lumbar puncture in all cases of old syphilis before the commencement of treatment.

Dr. Joseph Collins of New York said he did not mean to decry lumbar puncture as a means of diagnosis, but he would say that it was not comparable in any way with the ordinary symptoms. Syphilis wrote its signature on the soma of the individual in a way that the person who had learned to interpret the signs could never fail to read. That was an axiomatic fact. There was no such a thing as syphilis of the central nervous system that did not reveal itself in demonstrable ways, first by disturbance of the pupilary light reflexes, which he would venture to say never occurred in any other condition than syphilis of the central nervous system. He disregarded it as occurring in alcoholism. Impairment of the auditory nerve would be found in every case of syphilis of the central nervous system by adequate examination of the nerve centers. Early lumbar puncture would not reveal syphilis of the central system as well as would careful examination. He had records of lumbar punctures made by his assistants and he found that they did not furnish the information that was obtained by careful physical examination. About thirty new patients came in daily to the Neurological Institute and out of those thirty ten were lumbar punctured; they were sent to bed one day and went home the next day.

Dr. M. J. Rosenau of Boston said, in reference to the Wassermann, that it was a crude test, and in any series of cases the number of positive results might be dependent on the sensitiveness of the antigen used. Therefore unless they could standardize the Wassermann test particularly with regard to the sensitiveness of the antigen, the interpretations might be incorrect.

Dr. H. F. Swift of New York said, with reference to the point brought out by Dr. Rosenau, that he would like to call attention to the paradoxical Wassermann reaction. If one followed the reaction with the two methods—the icebox antigen and the cholesterin antigen with the warm technique—one would often find cases which would give a positive reaction with one method and a negative one with the other. And one could not tell which antigen was going to give a positive reaction in any given case. They should all bear this in mind; results from different laboratories had also often given contradictory readings because of this very fact. One should know this and consider it important that both methods be applied.

Some Findings in 3,000 Consecutive Medical Cases with Wassermann Examinations.—Dr. G. Dock of St. Louis, Mo., presented this topic, using charts to illus-

trate his talk. He stated that he had had Wassermann examinations made in all his medical cases. No attempt was made at clinical analysis while the work was in progress. In the technique three antigens were used: (1) Ordinary; (2) cholesterin; (3) Noguchi. Dr. Dock showed on charts the proportion of positive Wassermanns in different classes of patients: private, paying-ward patients, nonpaying patients, out-patients; and the proportions in different services: gastrointestinal, neurological, tuberculosis, etc. Results varied widely. In the white out-patients a positive Wassermann occurred in 52 per cent. In the colored out-patients positive Wassermanns occurred in 48 per cent. In the tuberculosis clinic there were 23.6 per cent. of positive reactions obtained. The latter figure was in contrast to what many authorities stated in regard to such cases, namely, that all chronic tuberculosis cases showed positive Wassermann reactions.

Dr. Hideyo Noguchi of New York described his technique and his method of increasing the sharpness of the reaction by using an acetone and alcohol-soluble antigen.

Chemistry of the Blood in Scurvy, Especially Its Calcium Content.—Drs. A. F. Hess and J. A. Killiam of New York presented this communication. Dr. Hess stated that there had been practically no metabolism work done in scurvy. The little that had been done was conflicting. The authors carried out various chemical examinations of the blood in cases of infantile scurvy. These included the CO_2 content, urea, sugar, calcium, and other constituents. The blood was found to be normal in all but two particulars. There was a slight increase in acidity, a mild degree of acidosis; and the more important finding was a decided decrease in its calcium content. As the amount of this salt was approximately normal in rickets, the difference emphasized the essential distinction between the two diseases. In spite of the low calcium content, the children did not show evidences of tetany or have convulsions, which proved that the body had a considerable factor of safety in regard to its minimal calcium requirements.

A Case of Eosinophilic Polymorphonuclear Leucemia.—Dr. H. Z. Giffin of Rochester, Minn., reported this case, the clinical characteristics of which were: splenomegaly; enlargement of superficial lymph glands; a white blood cell count which showed 73.6 per cent. eosinophiles, and polymorphonuclear leucocytes 24 per cent. The man had had edema and ascites in 1911, with enlargement of the superficial lymph glands, and eosinophilia. No parasites were found. He improved on medical treatment. He had splenectomy in 1915, and apparently did well after that operation. He lived until the fall of 1918, when he died of pneumonia and empyema. Eosinophilia was constantly present. At autopsy cosinophiles were found in all the hematopoietic organs. Dr. Giffin stated that eosinophiles originated in the bone marrow and also in other tissues of the body, especially in lymphoid tissue. The theory of the derivation of eosinophiles from hemoglobin was not proved. Little was known about the function of the eosinophiles; they seemed to have some connection with intestinal secretion, and were antagonistic to foreign proteins. Eosinophilia was present in scarlet fever; the highest count of eosinophilia was found in association with parasites (trichinæ) and with asthma. It was rare to find more than 25 per cent. of eosinophiles in the white blood cell count; eosinophilia rarely occurred with hyperleucocytosis.

Dr. L. F. Barker of Baltimore said he had observed one case with 71 per cent. of eosinophiles. The histology of the spleen was important in the findings in these cases. In splenomyelogenous leucemia the patellar reflex was diminished. He had made a lumbar puncture in the case referred to, and had got a fluid with a large number of white cells with typical myelocytes.

Dr. Emanuel Libman of New York said that there was no doubt Dr. Giffin's case should be called leucemia. A similar case had recently been reported by Dr. Louis Shapiro of Paterson, N. J., at a meeting of the New York Pathological Society. It was interesting to note that in the case described by Dr. Shapiro, as well as in the one described by Dr. Griffin, prominent symptoms were general edema and ascites. It might prove that these were characteristic symptoms of the disease. The tendency of edema could not be explained by the presence of the eosinophilic cells, because in trichinosis the edema usually occurred early and not late when the eosinophiles were very much more abundant. In the opinion of the speaker, the splenectomy in Dr. Griffin's case had no relation to the course of the disease, because in Dr. Shapiro's case the early clinical course was exactly the same as in Dr. Griffin's case, and no splenectomy had been performed. Dr. Shapiro had the opportunity of examining the bone marrow in his case, and in it had found a very marked proliferation of eosinophilic cells.

Dr. A. S. Warthens of Ann Arbor, Mich., said, in regard to Dr. Barker's statement of obtaining eosinophiles in the spinal fluid,—that the leucemic infiltration of the meninges was found in leucemia and also in chloroma.

Dr. F. W. Peabody of Boston mentioned the case of an Italian, 40 years old, who had a history of progressive weakness, and a spleen which reached to the level of the umbilicus; he had a white cell count of 50,000 with 2 per cent. eosinophiles. The patient lived a long time.

Dr. A. Krumbhaar said that lack of eosinophiles and their temporary disappearance in the peripheral blood had been found to occur experimentally in dogs. Eosinophilia occurred in mustard gas poisoning.

Dr. J. A. Capps of Chicago said he recalled one case he first saw as a case of splenomegaly. That patient refused operation and lived 11 years; he had a white blood cell count varying from 11,000 to 21,000, and a large spleen; was in fair health, and had eosinophilia that ran from 10 to 18 per cent., and very few myelocytes. The case was called one of leucemia.

Dr. Giffin, in closing, said that the microscopic examination of the tissues in this case would argue against leucemia.

A Long Remission in Pernicious Anemia.—Dr. Charles G. Stockton of Buffalo, N. Y., reported this case. The first report of the patient was that he suffered from pernicious anemia in 1899. It was of a serious character, with gradual improvement, and with interruption for six years. Following that, there was a disappearance of symptoms, excepting the continuance of achylia gastrica. During 1917 the patient was apparently well, except for the continuance of achylia gastrica. In February, 1918, he had a severe relapse, the blood showing characteristic morphological changes, although the color index was .8. The condition was grave and a transfusion of 900 c.c. of blood resulted in temporary improvement. A few weeks later the patient died of lobar pneumonia. The point emphasized was that the patient had a remission of twelve years. This would seem to discredit the theory that patients sometimes recover from pernicious anemia. Attention was then called to a severe anemia in horses, suggestive of pernicious anemia and dependent upon the infection of the gastric mucosa by the larvæ of the fly *Œstrus equi*. The writer thought that the gastric condition in pernicious anemia had not received sufficient attention.

Transfusion of Blood in Pernicious Anemia: Report of an Interesting Case.—Dr. J. M. Anders of Philadelphia presented this subject. He said that the chief aim of his paper had been to validate the claim made by certain writers that transfusion offered more for progressive pernicious anemia than any other form of treatment. The theory of toxic hemolysis was accepted to explain the genesis of the disease, although brief reference was made to Seyderhelm's experiments, which appeared to show that the injected non-hemolytic fragments of larval substance of the fly, *Œstrus equi*, found in the walls of the stomach of the horse, produced the characteristic symptoms of the severer types of anemia. According to certain writers, prime importance attached to oral sepsis as the cause. Barker had detailed a form of combined causal and symptomatic treatment, which rendered transfusions of blood unnecessary. On the other hand, Leyton, Kimpton, and others, claimed that this procedure offered the greatest chance of improvement to sufferers from pernicious anemia. It was highly probable that transfusion of blood owed its beneficial effects to the stimulation of the antihemolytic properties of whole blood, although the possibility of its power to increase

the activity of the bone marrow, should also be recollected. In the case seen by the writer, in consultation, transfusion produced a prompt remission lasting seven months, after the patient was thought to be lost. A second transfusion was followed by a remission, though less promptly, and at present, more than one year after the first transfusion, the patient had declared that he had not "felt so well for fifteen years." The blood picture, as well as the general health, had been greatly improved by both transfusions. This case impressed the writer with the need for a survey of the recorded experiences of clinicians and surgeons with the procedure during the decade last past, Warner and Schultz having given a complete bibliography up to 1910. The writer said he had collected 449 cases in which 1,082 transfusions had been made, figures large enough to base thereon a fairly accurate estimate of the value of the procedure. It was found that in 56.3 per cent. of the cases transfusion induced a remission, or brought about "marked improvement," which was equivalent to saying that a remission of greater or lesser degree occurred. Repeated small transfusions were to be preferred to single large ones, since they were free from dangerous reactions. Again, it was unwise to wait until the hemoglobin fell to or below 20 per cent., although often in these advanced grades, transfusion offered the possibility not only of averting death, but even of initiating one of those quiescent periods so characteristic of the disease. Early transfusion was to be advised and encouraged, especially in view of the fact that whole blood could be, thanks to the recent advances in vascular surgery, transferred safely, from donor to recipient, if proper precautions were taken. According to the collective investigations mentioned, transfusion offered more for this incurable disease as a means of prolonging life than any other form of treatment up to the present day, including splenectomy, which, moreover, caused immediate death in a not inconsiderable percentage of cases. Casual treatment and the routine method of administering arsenic might be combined with transfusion of blood.

Dr. J. R. Miller of Baltimore, Md., said that these long remissions in pernicious anemia had led some men to report cases of cures. The longest remission he had seen was of seven years' duration. Another interesting point was that he had seen a patient a few years ago who had a splenectomy done. At that time he had no nervous symptoms. He had a remission for about six months, but during the time his anemia was improving he developed marked nervous manifestations. Whatever was responsible for the change in the central nervous system developed as the anemia improved. Another case was seen in which the remission lasted six months and during that time the patient's color changed from a lemon yellow to that of a man who lived out in the sun.

Dr. G. G. Dock of St. Louis, Mo., said that he thought it important to report these cases of remissions. Several years ago he mentioned a patient who had lived for thirteen years. He heard every Christmas from a patient whom he first saw in 1906; he had had neuritis, as a result of Dr. Cabot's cure by Fowler's solution, but had been practically well all the time.

Dr. T. B. Futcher of Baltimore said he wished to cite a case admitted to his care at Johns Hopkins in 1908—a woman with a characteristic picture of pernicious anemia. In 1917 she was readmitted with the first marked relapse. That was a case in which the disease had lasted at least ten years. Unlike Dr. Stockton's case, her blood showed features of pernicious anemia. She was still in a period of relapse.

Dr. Frank Billings of Chicago said that one who had watched a great many of these cases must realize that there were grades and types. In 1896 he had a patient who suffered from pernicious anemia, though apparently the cause was a sharp attack of influenza. He recovered so well that he could do work as a night watchman for ten years. He always had a subnormal red cell count, and he occasionally showed nucleated cells. He had achylia gastrica during the entire time. He came into the hospital with a relapse; his blood went down to 600,000 reds, and hemoglobin 10 per cent. Another case was that of a woman who apparently recovered without transfusion and who lived thirteen years. There was something curious about pernicious anemia; there was a toxin or perhaps more than one toxin. In 20 per cent. of cases there were changes in the spinal cord. In treatment, removal of the spleen or transfusion would have effect in some cases but not in others. He said he believed many of the cases of reported cures after splenectomy were not cases of pernicious anemia at all.

Dr. F. Friedenwald of Baltimore said that he had examined a large number of cases with reference to the gastric secretion and he could confirm Dr. Stockton's remark that there is absence of gastric secretion. In those cases in which there was absence of gastric secretion one never found a return of the acid again, not even in the remissions.

Dr. R. C. Cabot of Boston said that he had seen about 800 cases; the case that Dr. Dock spoke of that had survived the speaker's treatment was the only case on his list that was still alive. Another thing about the disease was that there were suggestions made from time to time about its cause, but none of them appealed to him personally. In regard to therapeutics, he thought that the present wave of enthusiasm for transfusion would fall like the red cell count in this disease. It was perfectly clear that one could incite a remission by transfusion more reliably than by any other method, but that the cases lived any longer seemed to be not yet shown. And what had not been mentioned was that transfusion was not without its dangers. He had had one fatal case in which the blood was carefully grouped. The patient died within twenty-four hours after transfusion. Unfortunately, there was no post-mortem. He had also seen a case of sudden transverse myelitis, which, it seemed to him, must be thought of as a vascular phenomenon, possibly thrombosis. He had seen reference to this in the literature. One could not say, therefore, that transfusion was without danger, but it was a tempting measure because one could almost always promise a patient under fifty that he would get better.

Dr. Emanuel Libman of New York said that personally he thought a transfusion properly carried out was without risk. The difficulties came from hasty testing of the bloods, transfusing too large an amount of blood, or technical errors in doing the tranfusion. In the paper by Dr. Ottenberg and himself it had been shown that the transfusion did not influence the achylia nor change much the symptoms due to disease of the nervous system or of the tongue. These phenomena were due to the same toxic cause that produced the anemia, and were not dependent upon the latter. He drew attention to the large amount of valuable information concerning the value of transfusion and splenectomy contained in the papers by Drs. Minot and Lee. From his own more recent studies he could not convince himself that transfusion would start a remission, unless such remission would have later occurred spontaneously. In other words, the transfusions seemed to hasten the beginning of remissions and seemed to make them last longer. Even if one were to conclude that transfusions did not prolong life much, the patient certainly was in much better condition during the time that he lived.

Dr. Anders, in closing, said that transfusion was not done during the remission but only when there was a progressive downward tendency. It should be done before the hemoglobin dropped too low. In those cases one got good results in a large percentage of cases. He was sure his own case would not have been alive today if he had not been transfused. As to the duration of life—while it might not be true in some cases that life was prolonged, it must be true in others. The only way to know the proper time to do transfusion was by making blood examinations, and search for reticulated cells, and in that way the proper time for transfusion would be ascertained.

Experiments with Cultures of Streptococci with Special Reference to Empyema.—Dr. F. P. Gay of Berkeley, Cal., read this paper. His interest was aroused by the large numbers of cases of empyema in the army camps. Considerable advance had been made in the surgical technique, and a vast amount of work has been done on vaccines. The fact that typhoid vaccination succeeded was no reason why one should not get the same results with streptococci. Each organism was a law to itself. There was a multiplicity of forms of strepto-

cocci. There were two types of streptococci involved—the hemolytic and the nonhemolytic or viridans. *Streptococcus pyogenes* was divided into a number of groups. The production of an active immunity was a very difficult matter. The culture worked with was pathogenic for rabbits. The writer succeeded in producing empyema in the rabbit by injection of the culture into the pleural cavity; he had not succeeded in producing empyema by introduction through the respiratory tract. The cultures which would produce empyema would not produce septicemia; the organisms remained in the circulation for three or four days, but the animal did not die. The culture would not produce peritonitis. As regards the possibility for specific therapy, vaccines under the ordinary conditions, such as were used in the vaccination of human beings, had had no effect in preventing this empyema. In the case of animals, the animal was rendered more susceptible, except by long continued inoculation for six weeks or more, when the animal was rendered immune; but no serum or vaccine capable of curing the animal of empyema had been obtained. Dr. Gay had grown cultures on rabbit's serum and on dextrose. Each culture worked equally well, and both protected equally well. It was, therefore, not necessary to have an homologous serum.

Immunological Relationships Between Strains of Streptococcus Hemolyticus.—Dr. A. R. Dochez of New York presented this paper. He said that in certain conditions the streptococcus caused empyema more frequently than did the pneumococcus, which was the reverse of what normally occurred. The study of streptococci obtained during the wave of empyemas at a Texas army camp was made with the view of producing a serum. Many organisms could gain entrance to the body through the mucous surfaces. There were analogues of all organisms, which one did not understand. It was necessary to differentiate the pathogen from the saprophyte. They had studied 125 strains of *Streptococcus hemolyticus* isolated from bronchopneumonia sputum, and from the bronchial mucous membrane after death, from empyema following measles, and from cases of lobar pneumonia. The organisms were identified as *Streptococcus hemolyticus*. Discussion had centered about the question whether this group was a unit or not. There were certain reactions of agglutination and of protection which had been of service in this work. Certain concentrations of salt solution would produce agglutination of streptococci, when added to distilled water. The results of this study had been to show that there were certain immunological differences between different strains of *Streptococcus hemolyticus*.

Dr. Augustus Wadsworth of Albany, N. Y., said he would like to ask Dr. Gay if he found any difference in immunizing with dead cultures and living cultures in the protection of his animals.

Dr. F. P. Gay said they had not succeeded with dead cultures.

An Antihemolysin for the Hemolysin of the Gas Bacillus.—Drs. W. W. Ford and S. R. Miller of Baltimore presented this paper, which was read by Dr. Ford. The writer said that one of the first characteristics of this hemolysin of the gas bacillus was its ability to destroy the red blood corpuscles in man. The theory that this destruction of blood was produced by the acid formed by the bacillus was not tenable. The property of splitting up of blood was due to an excretory product from this organism. As a rule, there was no hemoglobinuria in these cases. In pernicious anemia there was no hemoglobinuria, which might point to the fact that the destruction of the blood might be a secondary condition and not a primary one. Inoculation of animals with the gas bacillus did produce hemoglobinuria, according to one observer. If destruction of the blood was an important feature of the gas bacillus, the production of a serum might have practical value. One would be loath to come to any conclusion on this matter, however. As said in the paper on pernicious anemia, there was some toxin absorbed from the intestine which produced this blood destruction. In the intestinal tract were organisms which could digest blood. Whether a toxic substance in the stomach or intestinal tract could be absorbed into the body was questionable.

Dr. H. Noguchi of New York asked if this hemolysin was unstable or whether it could be separated from the protein molecule.

Dr. Ford, in closing, said the hemolysin was stable, but could be destroyed at 60° C. He was not sure whether it was identical with the substance found by Dr. Bull in milk cultures. If one took milk cultures of gas bacillus and destroyed the hemolysin, one still had a toxin left. The hemolysin was precipitable by alcohol; it was digested by pepsin and pancreatin.

(To be continued.)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Held Wednesday, May 7, 1919.

The President, Dr. William J. Taylor, in the Chair.

An Early Publication on Vaccination.—Dr. William M. Welch presented to the College a pamphlet which was the first publication in this country upon vaccination. The article was written by Benjamin Waterhouse, the first Professor of the Theory and Practice of Medicine in Harvard University. The pamphlet states that the author received the virus from England and immediately vaccinated his own children. To prove that the children were immune he subsequently took them to the smallpox hospital in Boston, where they were inoculated with smallpox virus taken directly from a pustule on a patient in the hospital at that time. Finding that it made no impression upon the children he explaimed, "One such fact is worth a thousand arguments."

The Human Machine in the Factory.—Dr. Frederic S. Lee of New York stated that in 1913-14 the Marcy Institute in France undertook the investigation of industrial fatigue; that the coming on of the war had prevented a realization of the plan, but did exactly the reverse in England. The paper consisted largely of the results of the work done in England and in America during the war. Of a number of technical physiological methods used for the detection of fatigue three were mentioned: The spring-balance method of determining muscular strength, the vascular skin reaction test, and the cinematographic method. The spring-balance method, devised by Professor E. G. Martin, measured in pounds the force required to overcome the contraction of certain selected groups of muscles, and computing from such figures the total strength of the body was to be ascertained. In the vascular skin reaction test, devised by Professor A. H. Ryan, it was explained that a stroke is made with a suitable apparatus across the skin of the forearm. A white dermographic streak appears, increases in intensity, and gradually fades. The time elapsing between the making of the stroke and the termination of the maximum whiteness of the streak is shorter in fatigue. An index of fatigue is thus obtained, and a diurnal curve of fatigue might be plotted. Interpreted in physiological terms the curve revealed the progressive course of fatigue during the two spells of the day's work and the interruption of the fatigue process, or even a partial restoration of working power, during the luncheon period. The cinematographic method had been used both in France and America to present in graphic form bodily positions and bodily motions. It indicated the difference between the skilled and the unskilled worker. Amar had combined the cinematographic method with a method of tambour registration of physiological movements and had thus demonstrated the greater rhythmicity of the skilled worker's motions. The diurnal course of output, a method which had been extensively studied in America, was found in a dexterous operation requiring careful attention and exact neuromuscular coordination, to be as follows: Beginning rather high in the morning the curve rose still further and reached its highest point during the second hour of the forenoon; thence it fell gradually until the luncheon period; beginning at a slightly higher level after luncheon, it again rose momentarily, but only slightly, and then fell progressively throughout the rest of the afternoon, reaching its lowest point during the final hour. To increase the total output there was suggested the possible value of introducing other rest periods than the luncheon period in the working hours. The results in an experiment

in which two ten-minute rest periods were introduced showed an increased daily output of from three to twenty-six per cent. The studies indicated that the proolem of the length of the working day had its physiological features, and further investigation, the author predicted, would show that the optimum duration varied with both the nature of the operation and the worker: one length of day was best for certain kinds of work and certain workers, and another was best for another work and other workers. The establishment of a universal working day would therefore be an unscientific procedure. The indication that night work was not as efficient as day work was supported by the British observations showing that the output of the former was 6 to 17 per cent. less than the latter. In the seasonal course the output had been shown to be 10 per cent. less in August than in January, while by good ventilation this seasonal variation could be considerably counteracted. Most industrial accidents, it was believed, had a physiological origin and here it was fairly conclusive that fatigue was potent, the greatest number of accidents occurring in the final hour of the day's work. In observations upon the work of the human machine there was seen a new science, that of industrial physiology. So far as the human machine was concerned science ought, in the author's opinion, to be the guiding influence in the organization and administration of industrial enterprises. As science had changed the aspect of medicine it had a mission to perform in industry and in this regeneration it was believed America had a great opportunity for leadership.

Results of Nutritional Surveys in United States Training Camps.—Lieutenant-Colonel JOHN R. MURLIN, M. C., U. S. Army, said that one of the first activities of the Nutritional Surveys Division was to select men experienced in food survey, send them to the camps in rotation, having them select typical menus and make quantitative studies in order to determine the quantity of food needed, the quantity wasted and the suitability of the food for the need of the soldier. These surveys began about the 1st of October, 1917, and had continued almost to the present time. Because of many constructive efforts on the part of the survey members, the camp commanders requested that these nutritional officers be allowed to stay longer in the camps. This led to a general order, issued about the 15th of July, that a nutritional officer be stationed in a camp of more than 10,000 men. Meantime nutritional officers had been trained and sent to France and assigned to the separate divisions. In October of last year a request had been received from the other side that each division coming to France have a nutritional officer assigned to it. Obviously, every mess official in camp could not be individually instructed, and the nutritional officers had therefore gathered together the mess officers and sergeants and directed that they see that instructions were carried out. The work was appreciated to such an extent that those men had been kept in France and meantime had found much to do in connection with the relief work. As a result it was known what a laborer needed in the way of food, and much other scientific knowledge upon the question of the nutrition of the soldier in France had been acquired. In the continuance of this work the Army Medical School had established a laboratory for the instruction of medical officers in food nutrition. Work in sanitation would be applied in the inspection of foods in order to insure a properly balanced diet for the soldier.

Dr. JAMES M. ANDERS said that while the worker must be skilled in his special line of work, the care of the body was but little, if at all, less important from the viewpoint of efficiency. Apart from the question of keeping the worker in fit condition, the employer must bear in mind that he was dealing with a human being who had certain social claims which must be respected. Employers of labor should be encouraged to develop the so-called social conscience. From observation of men in service it would seem that in physical exercise there was a remedy not only for rapid fatigue, but one which would have greatly reduced the percentage of rejections among drafted men had it not been neglected in the past. From Dr. Lee's significant statement that physical exercise tended to increase a man's resistance to the effects of the fatigue poisons it was obvious that such exercise would make for greater efficiency of the human machine.

Dr. MURLIN, referring to the restoration effect of the lunch period mentioned by Dr. Lee, said he wondered if the restoration effect upon the worker varied according to whether the lunch was hot or cold, or whether it was a light lunch or a heavy one with meat.

Dr. ALFRED STENGEL observed that the results of the nutritional surveys had shown an experimental study of nutrition on a large scale; even more, perhaps, had the issuing of rations been experimental medicine on a large scale. The work done, particularly in England upon the rationing of the civilian population was experimental medicine of the highest possible order.

Dr. LEE, in closing, regarded the question raised by Col. Murlin as of the greatest importance. The efficiency of the human machine in the factory was largely dependent upon adequate and properly balanced diet. British investigators had placed a minimum diet of 3000 calories for munition workers, but had made no observations on the correlation of rations and output. He wished that Col. Murlin might be induced to undertake such a study.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Miscellany.

Crisis in the French Pharmaceutical Industry.—Laumonier in the *Gazette des hôpitaux* for June 7 discusses a subject already familiar to many readers. Germany's prestige ceased in August, 1914, and while a few of her synthetics were also manufactured in France some of the more important were cut off. The French chemists, however, succeeded in making substitutes for the latter. But unfavorable conditions for manufacture ultimately developed—chiefly coal shortage which was a menace until by close cooperation the industry was placed on a remarkably good footing. The chemists were closely affiliated with the subsidiary and associated industries and with the coal miners until a complete system of interpenetration resulted. Nevertheless, the fight with the renewed German drug industry will be severe. Great Britain and the United States have also prepared to compete with the new Germany, and they excel in raw material although the excellence of production rests with the French, says the author. Competition with these two countries is much less to be feared than competition with Germany. The abundance of coal and the fact that the blockade did not hit the raw materials make it evident that the coaltar synthetics, dyes, and perfumery can be placed by the Germans on the market without delay, especially on the French frontier, in prices which defy competition. It is feared that the morale of the French merchants has become lowered and that they will be too conservative to fight the German monopoly. During the war, steps were not taken to meet post bellum conditions. It is the old case of not mending the roof because of the rain. Moreover, there is strong competition between French drug firms and while this was but moderate during the war it is apt to reappear now and defy cooperation.

The "Vision" of Andres Laguna.—According to Albinaña Sanz, in *El Siglo Medico* for May 24, Andres Laguna, a Segovian physician, anticipated the activities which are now taking place at Versailles. He was the most erudite man of his day, physician in chief to the Emperor Charles V, to King Phillip II, and to two popes. He wrote and translated industriously and was noted alike for encyclopedic knowledge, diplomatic gifts, and oratorical ability. In the year 1544 the European situation could not have been worse. The peace of Crespy was the final point of discord between Francis I and Charles V. Both coveted the same territory and the people in Savoy and the Province were the latest to be slaughtered. A murderous pestilence spread from Lorraine and all in all conditions were extremely like those during the present war. Religious antagonisms everywhere added fuel to the fire. The eminence of Dr. Laguna and his many talents caused him to be summoned to Cologne where he was requested by the university to deliver a dissertation calculated to soothe the political and religious conditions of the moment. This he delivered on January 22, 1545. The staging of the affair was most lugubrious, suggesting a funeral ceremony. The orator likened Europe to a woman who was sad, weeping, pallid, and mutilated as a result of the fratricidal war waged by her sons. Opulent cities had become rubbish, fields were barren of trees, temples ruined, altars demolished, matrons prostituted, virgins dishonored, boys carried away, commerce and manufactures destroyed. Laguna might here be speaking of the work of the Germans in Rheims, Louvain or Liège. His speech, circulated broadcast, caused a profound sensation and a notable reaction against the war spirit.

Nearly four centuries have elapsed and we find much the same conditions prevalent. Laguna's efforts at that epoch were idealistic and he was the pacifist of the day as well as the peace maker. Curiously the peace movement then was initiated by the Germans, while today the destiny of that people is menaced with the prophesy that their state will become a "second Spain." To extend the comparison further the Germany of that period was merely a sort of appanage of the then imperial Spain. Save for the fact that Laguna acted in a private capacity, one can see marked similarities between him and some of the peace commissioners. Like Clemenceau he was a physician, and his persuasive oratory suggests Lloyd George. Those fond of analysis might find further points of resemblance between Laguna and his remote successors.

Fathers of Physiology.—Professor Richet has been giving a course of lectures on the masters of physiology for the especial advantage of American medical students in Paris in which he seeks to show that this science did not actually originate with the men usually credited with pioneership but with great philosophers like Descartes and Lavoisier. The former dealt with method and evidence. Unlike Bacon he could make good in his own person, as he showed by his creation of analytical geometry. He was over 40 when he got around to the biological sciences. It is not generally known that he performed vivisection experiments to corroborate or refute dead house finds. In his own person he was anatomist and experimental physiologist. Once asked by a visitor to show him his library he led him to the carcass of a calf in course of dissection. His physiology was largely mechanical in conception but he employed the expression "nervous vibrations" and other modern phrases. As physiologist he was rather destructive than constructive as became his time.

In regard to Lavoisier his reputation as a very great scientist is ever increasing. Like Descartes he traveled extensively in youth, a great quickener of the intellect. When hardly more than a youth he was immersed in practical chemistry and this led to his immortal experiments of 1773 which culminated in his doctrines of respiration. During the decade 1773-1783 chemistry and with it p[illegible]siology was revolutionized. His career as a sta[illegible]man and martyr is of course well known t[illegible]rance's greatest man was killed by the F[illegible]. He had demonstrated his wonderful disc[illegible] the humble guinea pig—how life is c[illegible], oxidation. He even demonstrated t[illegible] change as it occurs in muscle. Richet c[illegible] that Lavoisier's work was sufficiently g[illegible]stify the term that be given him of the f[illegible]hysiology.

PULMONARY SUPPURATION.*

BY C. A. HEDBLOM, M.D.,

ROCHESTER, MINN.

SECTION OF THORACIC SURGERY, MAYO CLINIC

PULMONARY suppuration is a comprehensive term. Anatomically the bronchi or the parenchyma alone may be primarily involved, or the pulmonary infection may arise by perforative extension from an adjacent structure. Pathologic subdivisions of the term are abscess, gangrene, bronchiectasis, and purulent bronchitis.

Gangrene of the lung is largely a pathological distinction. Typical cases of massive gangrene may be recognizable clinically but all intermediate gradations of abscess and gangrene occur. Each may supervene on the other. When we diagnose pulmonary gangrene and when we get it for treatment it is almost always accompanied by suppuration; it is abscess and gangrene.

On a therapeutic basis suppurating tuberculous cavities, purulent bronchitis, and diffuse bronchiectasis are excluded. A localized bronchiectatic process on the other hand often cannot be differentiated clinically or by *x*-ray from abscess. The distinction may be difficult to make at operation also. For the purposes of this discussion, therefore, localized bronchiectasis is included with abscess and gangrene.

Historical.—Hippocrates taught that a pulmonary abscess that had burst into the pleural cavity could be healed by draining the latter. Schenk, in 1584, is credited with a case in which he promoted spontaneous rupture by fomentations, etc. Even though this may have been an instance of empyema necessitatis it constitutes evidence that the occurrence of pulmonary suppuration was recognized at this date. Baglivi, 1696, is said to have been first to establish drainage by intercostal incision. Barry, in 1726, reported two cured cases and one fatal case following incision for drainage. Campardon, in 1759, described in detail the case of a patient with typical symptons cured by draining an abscess that pointed into the chest wall. Sharpe, in 1769, and Pouteau, in 1793, reported operative recoveries. In 1793 Gumprecht published a remarkable monograph discussing diagnosis, prognosis, and treatment. He states that before surgical treatment should be instituted it is necessary to determine the presence and seat of pus and the condition of the pleura as to adhesions. He cites several cases in which operation was successfully done, discards one as probably being empyema, and details the necropsy findings in one insufficiently drained, fatal case.

Further developments in the surgery of pulmonary suppuration was uncertain and slow. After another hundred years Garré was able to collect from the literature only 122 cases of abscess in which operation was done, and many of these he considered of doubtful diagnosis. The literature from 1800 to 1880 consists chiefly of individual reports of spontaneous cures and of postmortem findings. Huntington, in 1876, reported 32 cases from the Massachusetts General Hospital; these had been observed during the preceding eighteen years. None of the patients were operated on. Most of the operations in this period were trocar puncture, or incision of the abscess pointing into the chest wall. Intercostal incision and pneumotomy were performed by Faye, Bell, Jaymes, Zang, Hawthorn, Sutton, Stokes, Dickson, and others.

The uncertain results of thoracotomy stimulated search for other methods. Green, in 1860, attempted to catheterize the air passages to promote nature's method of drainage. He states that at various clinics injection of antiseptics into the bronchi had been frequently attempted. Mosler, Koch, and Fränkel, following animal experimentation, attempted sterilization of the lung parenchyma by the injection of carbolic acid, tincture of iodine, salicylic acid, etc. Mosler and others used carbolic acid irrigation of abscess cavities drained by thoracotomy.

The basis for the further development of the surgery of the lung was furnished by the results of animal experimentation, notably of Jaszenko, Gluck, Schmid, and Biondi. Of especial influence on thoracic surgery was the demonstration by Gluck and others that animals can survive resection of the lung. The prevailing conception that the brain, heart, and lungs—the tripod of life—are beyond the reach of surgical intervention was modified by the experimental proof that one lung, like other paired organs, is capable of functioning for both. Of the early clinical contribution perhaps the most important are those of Christian Fenger in 1881, and of Bull in 1881-1884. Fenger reported 5 cases from the literature and one case in which he had operated. Bull in 1882, reported 19 cases, 14 of which he considered beyond question as to the pathology involved. Runeberg, in 1887, published a critical study of 7 cases of abscess, 10 of gangrene, 2 of echinococcus, and 6 of bronchiectasis. In an important monograph published in 1897, Tuffier reported a series of 216 thoracic cases in which operation had been done; the series included 36 of cav-

*Presented before the American Association for Thoracic Surgery, Atlantic City, June, 1919.

erns, 49 of abscess, 45 of bronchiectasis, and 11 of foreign body abscess.

The accumulation of literature since then has been relatively rapid. In 1903, Garré was able to add 278 cases, and in 1912 he collected 182 cases,

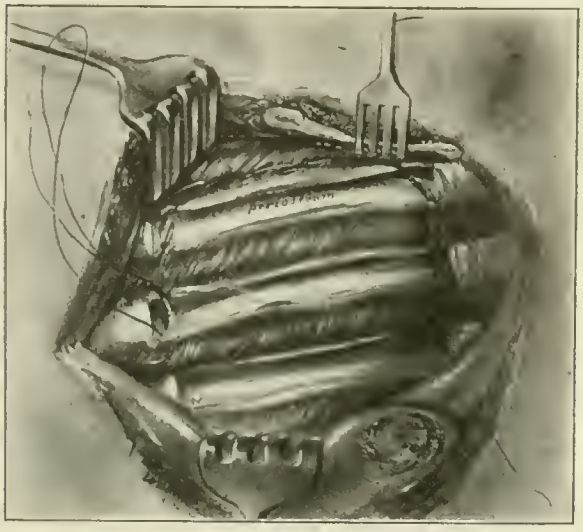

Fig. 1.—First stage operation, showing suture of lung to intercostal bundles and parietal pleura.

making nearly 600 in all. The important series of personal cases of Körte, Lenhartz, and Külbs and several series of collected cases will be referred to in connection with operative results.

Up to 1919 seventy patients have been operated at the Mayo Clinic for pulmonary suppuration. The combined mortality from all causes, including bronchiectasis, was 33.3 per cent. The present study is concerned chiefly with 54 cases in which operation had been done since 1910. Eight of these cases were operated on by Beckman, 9 by Judd, and 17 each by Robinson and myself. There are included also 2 cases that progressed to a spontaneous cure and 24 necropsy cases. In 17 of the 24 necropsy cases abscess occurred as a postoperative complication; in 16 the abscesses were multiple. In 7 instances the patients were either moribund at admission or the condition was not recognized clinically. The grouping of these 80 cases may be seen in Tables I and II.

Table I.

Patients operated on for pulmonary suppuration:	
Acute abscess	30
Chronic abscess	17
Bronchiectasis	7
Spontaneous recovery	2
Abscesses found at postmortem:	
Surgical cases	17
Medical cases	7
	80

Etiology.—Primary suppuration of the lung is probably rare. It develops on a preceding inflammatory process or the infection is carried to the lung tissue through the bronchus, the blood stream, or by direct extension. Of the inflammatory lesions, pneumonia appears to be the most common. At the Massachusetts General Hospital Lord found pneumonia to be etiologic in 14 of 50 cases of abscess and in 8 of 50 cases of gangrene. Microscopic abscesses were found in 10 of 85 fatal cases of bronchopneumonia. Bronchopneumonia following influenza is often complicated by abscess, often multiple and usually subpleural. Oberndorfer in a series of postmortem studies reports the frequent occurrence of infarct like areas near the pleural surface of the lung. In the later stage these areas either become gangrenous or break down into abscess cavities. Oberndorfer also observed frequent purulent bronchitis, and bronchiolitis, in many instances with cylindrical bronchiectasis. Many other writers report similar observations.

Table II.—Age and Occupation.

From 51-60 years	11	Student	1
From 61 years	5	Druggist	1
		Bartender	1
Males, 65; females, 15.		None	5

The frequency of necropsy findings of abscess associated with pulmonary suppuration varies according to different observers. Bell reports 30 necropsies, Stone 55, and Ely 39 without pulmonary abscess. Hunt in 30 examinations found abscesses in 2, Wegelin in 68 found multiple small abscesses in 12. Coutant reports one. Opie in 200 necropsies found "suppuration" in more than 25 per cent. At the Mayo Clinic in a few more than 100 prolonged influenza pneumonic cases examined, abscesses were found in 3. Many cases have been observed clinically in which symptoms of abscess were present. In one instance the patient expectorated in twenty-four hours eighteen ounces of thick purulent sputum. This patient made a complete recovery after drainage of the empyema, probably following rupture of the abscess into the pleural cavity. In the available literature I have found no mention of operation for acute abscess complicating influenza pneumonia.

Deaver reports 13 cases of interlobar empyema in which operation was done; in many rupture into the lung had occurred. Weil had a series of 7 cases of gangrene of the lung following influenza. Pneumothorax following rupture of subpleural abscess

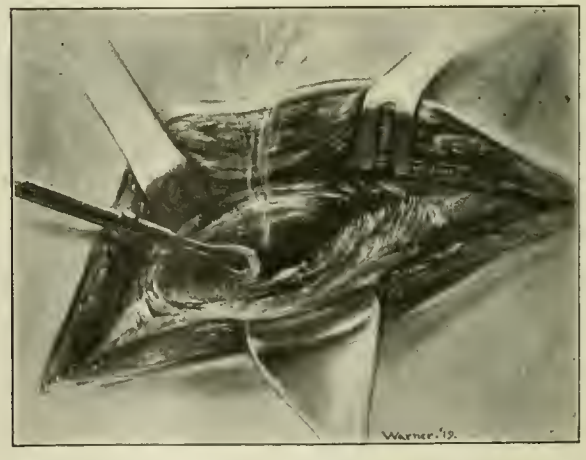

Fig. 2.—Second stage operation, showing burning of funnel-shaped opening through the lung tissue down to the abscess

is reported by the Influenza Committee of the British Armies in France, by Weber and by others. Within the past few months I have frequently observed empyema with bronchial fistulæ, presumably from small superficially situated abscesses.

Aspiration of infected material appears to be a more frequent cause of abscess than is generally recognized. Of considerable interest and importance are the apparently relatively frequent lung abscesses following tonsillectomy. A number of such cases have been reported recently. Claytor reports four cases with recovery. Frank found 5 in the records of the Michael Reese Hospital, Chicago, for the last ten years. In reply to a questionnaire sent to 50 internists, surgeons, and nose and throat specialists he learned of 15 others. Of these Warthin reported three postmortems in students. Bevan of the Presbyterian Hospital, Chicago, writes "we have certainly had from ten to a dozen abscesses in the last two or three years, many fatal, following tonsillectomy." Manges reports 6 admitted to the Mt. Sinai Hospital within six months. Scudder mentions several. Tewksbury reports having seen 15 in one year following nose and throat operations. Bassin has collected 19 cases with a 75 per cent mortality. Most of these tonsillectomies were done under general anesthesia. Five cases in my series of 56 followed tonsillectomy under general anesthesia done elsewhere. Coakley believes such cases are due to aspiration of blood infected by the cheesy or milky bacteria laden secretions squeezed out at operation, and that the infection is not embolic. The fact that following approximately 16,275 tonsillectomies performed at the Mayo Clinic from January 1910 to January 1919, there has not been a single known instance of abscess of the lung, is evidence in support of this contention.

Inhalation of infective material from the mouth or of a tooth during extraction is not an uncommon cause (Quincke, Schulz, and Külbs). Six such cases are herein recorded.

Aspiration of particles of food, mucous flakes, epithelial shreds, etc., probably occurs with sudden inspiration as in laughter, hurried eating, narcosis, stupor, deep sleep, following disturbances of pharyngeal and laryngeal innervation, etc. There was a probability of foreign body abscess in 12 of 41 cases reported by Külbs. Aspiration of fairly large organic bodies unknown to the patient should be borne in mind as a possibility in cases of suspected foreign body abscess in which the *x*-ray shows no foreign body.

Table III.—Etiologic Factors.

	Cases.	Acute Abscess.	Chronic Abscess.	Bronchiectasis.
Primary abscess:				
Pneumonia	13	7	4	2
Tonsillectomy	5	3	2	
Empyema	1		2	2
Teeth extraction	6	5	1	
Grippe	2		1	1
Foreign body	1		1	
Dust	1	1		
Trauma*	1	1		
Liver abscess	1		1	
Subdiaphragmatic abscess	1	1		
Abscess after other operations:				
Cancer of stomach	1	1		
Gastric ulcer	2	2		
Duodenal ulcer	1	1		
Appendicitis	1		1	
Questionable	14	8	4	2
Primary abscess not operated on:				
Tonsillectomy	1	1		
Pneumonia	1		1	
	56	31	18	7

*Followed by pneumonia.

In a series of 40 cases seen at the Mayo clinic a foreign body in the bronchus cast no shadow by *x*-ray in 23 cases. Twelve were peanut kernels, 6 kernels of corn. In 14 instances the foreign material had been present more than a month and in 7 more than two years. In one instance a tack had been in the bronchus for ten years and had not caused symptoms. In another instance a tack had been present unsuspected three and one-half years. The patient was sent to a tuberculosis sanitarium where *x*-ray disclosed the foreign body. Such an aspiration infection is possibly the etiologic factor in many cases of pulmonary abscess and bronchiectasis in which no definite cause can be ascertained.

The frequency of abscess from prolonged retention of bullets, shrapnel, etc., is of considerable interest at this time. Various authors, Dean, Elliott, express the opinion that abscesses following war injuries were very rare. Archibald, Gask and Wil-

Fig. 3.—(216141) Dec. 8, 1917. (Acute abscess) Plate taken ten days before operation.

kinson, Eggers and White, Bennett, Grégoire, Haim and others, however, report cases of abscess. Duval believes retained foreign bodies are always potential sources of infection. Turner, after four years' experience, writes that in operating in these cases he has often found localized collections of pus in connection with the foreign body. He believes many cases of infected hemothorax and empyema have arisen by perforation of such an abscess.

The etiologic factors in the 56 cases of primary suppuration herein reported are noted in Tables III and IV. In Table III it may be seen that in 14 cases (25 per cent.), the abscess developed on a preceding inflammatory lung condition; in 14 (25 per cent.), there was a presumptive evidence of the infection having been carried to the lung by foreign material (detritus during tonsillectomy, teeth, dust, other foreign bodies, etc. In at least 10 (18 per cent.), there was a possibility of infection by direct

extension from an adjacent inflammatory process (empyema, peptic ulcer, abscess).

*Operated elsewhere.

Preceding disease incidence in the 24 cases in which abscess was found at postmortem is noted in Table IV. In 6 (25 per cent), there was a preceding inflammatory process in close proximity to the lung. In 8 (33.3 per cent), operation was performed for malignant disease. The lesion was probably metastatic in 6 (25 per cent) of the infected cases; there was a preceding pneumonia in one case of malignant disease. Sixteen (66.6 per cent) of the whole group were cases of multiple abscesses; there was one of bilateral gangrene.

Symptomatology.—The most suggestive single

symptom of pulmonary suppuration is a chronic productive cough. Because the abscess has usually burst into a bronchus at the time the patient is first observed the sputum is usually frankly purulent. If the perforation has not yet occurred or if the drainage thus established is inadequate the sputum may be mucoid or mucopurulent and inconsiderable in amount. Sometimes it is watery and brownish from admixture of blood. Associated symptoms in varying number and degree are chills, fever, night

Influenced by gravity	8	Not stated	42	Not stated	14

A sudden onset of sputum during a paroxysmal coughing spell is usually considered as most characteristic of abscess. In this series the onset was gradual in at least half the cases, probably this was also true in most of the 15 cases in which the mode of onset was not stated. The amount of sputum varied from a few ounces to a quart in twenty-four hours. The odor was characteristically foul, notably so in some of the cases of probable inhalation abscess. Repeated examinations were made for tubercle bacilli in 42 cases. The one case in which bacilli were found was probably one of associated tuberculosis and abscess. The onset of sputum in this case was sudden and in excessive amounts. A syndrome

suggestive of tuberculosis may be seen in Table VI.

Not stated	21 cases

The physical signs in cases of pulmonary suppuration vary and their significance is uncertain. Associated thickened pleura, pleurisy with effusion, pneumonitis surrounding the abscesses, sequestrum blocking the bronchus of the affected area, varying amounts of pus in the abscess cavity and the distance of the abscess from the periphery of the lung are some of the variable factors which lead to uncertainty as to the presence, location and character of the lesion. Dullness to percussion seems to be the most reliable sign. It was present in 62 per cent. of these cases (Table VIII.).

Diagnosis.—The diagnosis rests largely in the

Fig. 6.—Same case as Fig. 5. April 11, 1918. Plate taken three and one-half months after operation. No symptoms, no sinus. Gained 50 pounds in weight.

presence of cough with sputum, on the clinical signs and symptoms of infection and on the *x*-ray. A history of previous inflammatory disease of the lungs or of possible aspiration of infected material is of decided value. X-ray examination is very useful, especially in the differential diagnosis, and in the localization of the process. The *x*-ray findings studied in the light of the clinical aspects of the case will usually lead to a correct diagnosis. In attempting to evaluate the comparative reliability of the

Fig. 7.—(228271) May 28, 1918. (Acute abscess) Plate taken just before operation

x-ray and clinical methods of diagnosis it must be borne in mind that the clinical diagnosis is usually made with the aid of the *x*-ray while the *x*-ray diagnosis is apt to be independent of the clinical history and findings. In some cases operation proves both methods fallacious, and, unfortunately, the postmortem examination at times reveals the failure also of the operation.

Table VIII.—Physical Signs.

Dullness to percussion		36 cases
Associated bronchial breathing,	8 cases	
Distant breathing,	17 cases	
Negative physical examination		2 cases
No record....		18 cases
		56

Twenty-four of these 47 cases were diagnosed alike clinically and by the *x*-ray. In 8 additional cases, in 4 of which the *x*-ray had not been used, the clinical diagnoses of abscess was proved correct at operation. In 8 other cases diagnoses were made clinically and by *x*-ray but no abscess was found at operation. In 5 of these 8 the abscess was found postmortem. In 5 cases proved at operation the clinical and *x*-ray diagnosis was empyema or subdiaphragmatic abscess. One case diagnosed gangrene clinically and pleuritis by the *x*-ray proved to be abscess. A diagnosis of bronchiectasis was made in only one case both by *x*-ray and clinically. In one questionable case the clinical diagnosis lay between abscess and bronchiectasis. In another case the *x*-ray diagnosis was "dense" infiltration.

In the differential diagnosis, tuberculosis, encap-

sulated empyema, generalized bronchiectasis, fibrosis, perforation of adjacent structures by the abscess and malignant disease are chiefly to be considered. Of these tuberculosis is the most common and the most important. Tuberculosis may be mistaken for suppurative disease but the error of mistaking a purulent lesion for tuberculosis is more frequent. Furthermore the association of the two conditions is undoubtedly more frequent than is generally recognized. In 17 instances in this series of 56 cases there was apparent evidence of a primary or of an associated tuberculous lesion. A more or less characteristic syndrome of tuberculosis was present in all of these 17 cases. Cough with sputum, hemoptysis, fever, night sweats, and loss of weight in varying combinations was present in all. A definite diagnosis of associated tuberculosis was made in 5. Tubercle bacilli were found in the sputum in one instance only. Seven of the 17 patients died, 9 improved or were entirely relieved of their symptoms by operation. A postmortem examination was made in 6 of the 7 fatal cases. In 2 a tuberculous process in addition to the abscess was found, in the other 4 a suppurative lesion, but no tuberculosis. Of the 9 patients who recovered eight were practically cured by operation and were well at the time of the last report—3 to 14 months. The detailed findings in these 17 cases are recorded in Table IX.

Fig. 8.—Same case as Fig. 7. Sept. 6, 1918. Plate taken three and one-half months after operation. Slight residual cough. No sinus. Gain in weight about 50 pounds.

An encapsulated or interlobar empyema, probably as a rule secondary to the rupture of a lung abscess, may present a confusing picture. The early history is likely to suggest abscess, the presenting symptoms and physical findings being those of empyema. The sequence of symptoms is of some significance. Trousseau stated that an abscess will burst through into the bronchus in from twenty to twenty-five days, and that empyema will break into the lung not earlier than the fortieth day. In the presence of a diffuse shadow shown by the *x*-ray it may be im-

possible to decide which perforation has occurred. If an encapsulated empyema is found at operation a funnel shaped depression in the lung may mark the site of an old abscess or there may be an open such cases makes a correct preoperative diagnosis of

Fig. 9.—(236782) June 27, 1918. (Acute abscess) Plate taken just before operation.

such cases make a correct preoperative diagnosis of less practical importance than if they were absent.

A circumscribed bronchiectasis may be difficult to differentiate from abscess. From the fact that either condition predisposes to and often is the cause of the other it follows that the two are often associated. In such cases, if a dense circumscribed shadow only is shown by the *x*-ray the diagnosis must be made on the history and symptoms. In the series of 7 cases herein reported the preoperative diagnosis was correct in only 2.

Malignant disease of the lung is comparatively rare yet not so rare but that it must be considered in a differential diagnosis. In three cases not included in this series exploration was done for lung abscess. One was a case of central growth, probably sarcoma; the patient died a few months later at home and, unfortunately, no postmortem was obtained. A second case was one of carcinoma, apparently primary, in the lung with associated bronchiectasis, a third was found at postmortem to be one of carcinoma of the left adrenal with metastasis to the left lung.

Another probably rare condition stimulating abscess is localized fibrosis of the lung. One such case was explored repeatedly for abscess but no definite focus was found. The patient is at present improving slowly, approximately two years following the onset of the symptoms.

Treatment.—The treatment of pulmonary suppuration is drainage. The anatomical relations of lung parenchyma, bronchi, and trachea, are such as to provide spontaneous evacuation once the abscess has opened into a bronchus. During coughing the lungs are compressed by the wall of the chest and by the diaphragm; this further aids in expelling the pus. The patients often discover that certain positions favor expectoration and so unconsciously make use of gravity to help empty the cavity. That spontaneous cures result in this manner is to be expected. Probably a great many cases of small abscesses in which the symptoms are mild are never recognized. On the other hand, a not inconsiderable number of unquestioned cases of spontaneous cures are recorded. Even abscesses perforating from the liver have been cured by promoting gravity drainage (McKechnie). Acute cases of a mild type, according to many writers of experience, may therefore be treated expectantly for a few weeks in the hope that drainage through a bronchus may effect a cure. Even in such cases it must be recognized that the presence of pus in the bronchial tree is a constant menace to other portions of the lung.

The mortality following expectant treatment in general was early found to be very high. Lenhartz, quoting statistics from three large municipal hospitals in Berlin, 1905, Verneuill, Picot, Kissling, Baron, and others reported it at from 60 to 100 per cent.

The operative mortality for gangrene in relatively large series of cases collected by Garré and by Picot was 29.3 per cent. and 29.5 per cent. respectively. Lenhartz, 1907, had a 37.6 per cent. mortality in 85 cases. Sauerbruch found the mortality following a

Fig. 10.—Same case as Fig. 9. Dec. 30, 1918. Plate taken six months after operation. Slight residual cough and sputum. Marked gain in weight.

drainage operation for bronchiectasis to be 35 per cent. in 123 collected cases.

Both mortality and morbidity are greatly reduced by early operation. This is strikingly shown by the reports of Freyham, Kulbs, Schulz, Scudder and

especially by Eisendrath. In a series of 53 acute and 40 chronic postpneumonic abscesses. Eisendrath found the operative mortality to be 11.3 per cent. and 35 per cent. respectively.

The mortality in 30 acute cases herein reported was 33.3 per cent.; in 17 chronic cases it was 47 per cent. The mortality following operation for abscess in several series of cases is indicated in Table X.

Table X.—Operative Mortality.

Author.	Year.	Cases.	Source.	Mortality, per Cent.
Garrè	1903	400	Collected	25

Külbs	1913	24	Personal	25
Hedblom	1919	54	Mayo Clinic	33.3
Hedblom	1919	17	Personal	23.5

The surgical treatment aims at facilitating drainage and healing of the abscess cavity either by carrying nature's method one step farther—collapsing the lung walls—or by drainage from the outside, and if necessary in chronic cases by mobilizing the chest wall to secure collapse of the cavity, and healing. The radical excision has been reserved for extreme cases of destruction of the lung substance and for bronchiectasis. The mortality following this radical procedure has been uniformly high. In chronic cases in which the abscess wall is rigid, collapse may be attained by rib resection. Radical rib resection operation was performed by Macewen in 1906. Perthes recommends a two-stage operation, mobilization of the chest wall being deferred until the patient's condition warrants it. Tuffier, in 1914, without opening the abscess, secured partial collapse of the cavity by separating the parietal pleura from the chest wall and inserting masses of fat. He has reported two cures by this method. Forlanini has adapted his artificial pneumothorax therapy for tuberculous cavities to those of pyogenic origin. In 1910 he reported a cure in a case of six years' duration. The treatment lasted twenty-five months. Izar reports one successful and one unsuccessful case. He refers to three others, among them one by Volhard, in which improvement followed the establishment of a complete pneumothorax, but the patient died in one month of empyema. Tewksbury has reported 10 acute and 2 chronic cases. Eight patients were cured, 2 were temporarily improved and 2 died, one of empyema. Artificial pneumothorax seems rational and promising in cases of deep seated abscess. It had been used elsewhere in two cases herein reported. In one there seems to have been some benefit, since hemoptysis was temporarily checked. In another case an extensive cellulitis of the whole chest wall resulted. The patient presented himself a year later with a huge chronic abscess which was drained. Two months after the operation he died of hemorrhage.

Robinson used pneumothorax therapy in one case of postoperative abscess with brilliant result. In another case of central abscess following gangrene, appendicitis and subdiaphragmatic abscess, the same treatment was attempted without result. In acute central abscess this form of treatment is certainly the safest and seems promising. The presence of pleural adhesions, however, in approximately 50 per cent. of cases will always limit the applicability of the method. Partial collapse of the lung has been effected by Bruns and Sauerbruch by ligating the major pulmonary arterial branches.

Thoracotomy with rib resection and pneumonotomy is the operation most extensively practiced and will probably remain for most cases the operation of choice.

The indication for operation is the presence of a purulent localized focus and marked characteristic constitutional symptoms that are not on the mend. The question of whether the process is acute or chronic, single or multilocular will modify materially the operative procedure and the prognosis, but operation is to be advised on principle. Localized bronchiectatic processes would best be placed in a separate group were it possible always to diagnose them as such. Bearing in mind the difficulty in diagnosis in this group of cases and the fact that localized abscess and gangrene may supervene on bronchiectatic foci, probably more harm than good would result from attempting to differentiate borderline cases. The decision as to operative interference in the desperately sick may be very difficult. Operation in such cases as a last resort will increase mortality statistics but it will save lives. The patient is entitled to his chance.

Anesthesia.—General anesthesia is favored more or less by many continental surgeons (Tuffier, Lenhartz, Kissling, Körte, Picot). Küttner, Quincke and Garré, Külbs, Murphy, and others prefer, whenever possible, local anesthesia. In my hands local and nerve trunk anesthesia has been very satisfactory. The safety with which a two-stage operation may be done by this method makes it possible to extend the operative indication to desperate cases in which general anesthesia would be prohibitive.

Operation.—The incision is made over the affected area as localized by physical findings and especially by the *x*-ray. If the focus is in a lower lobe a lateral or postero-lateral incision is usually best; if in the upper lobe anterior incision gives the best exposure. The presence of the scapula and thick back muscles limits the area that can be exposed high posteriorly. In two recent cases in which the abscess lay posteriorly and high, good exposure was obtained by resecting the angle of the scapula. An incision larger than seems necessary should be made. As has been well said: "better two ribs too many than one too few." One is continually impressed with the rapidity with which a wound in the chest wall heals. If the incision is not ample it will close to a small sinus before the cavity in the lung has become obliterated.

Subperiosteal resection of four inches of two or three ribs suffices for exploration. The further procedure depends on the presence or absence of adhesions of the lung to the parietal pleura. A thickened greyish opaque pleura indicates the presence of adhesions. In some cases without adhesions, the movement of the lung can be seen through the pleura. In other cases there may be adhesions in one part of the exposed area and not in another. In still other cases a small incision through the pleura may be necessary to settle the question. A safe procedure recommended by many thoracic surgeons, and one I have followed, is in case of doubt to proceed as though adhesions were not present.

If adhesions are not present or if they are doubtful, or only partial, as occurs in about half the cases, the pleural cavity is walled off by suturing the lung to the pleura and intercostal muscles with continuous catgut stitches after the method of Péan and Roux. Suturing through the intercostal tissue prevents tearing of the pleura and the added difficulties due to partial pneumothorax and retraction of the lung. Körte, in six instances, found it necessary to seize the lung with forceps and drag it out into the

wound before he could complete the suture. In one case, because of violent coughing, I encountered a little difficulty but the lung did not collapse. When the lung is sutured securely the circumscribed pleura may be opened at once without danger of lung collapse. But there is still danger of leakage along the suture line which also may tear. The empyema that may result is a serious and often fatal complication. Unless immediate drainage is indicated it is therefore safe to wait a few days before attempting to drain the abscess. Other or supplementary methods of protecting the pleura by provoking adhesions are iodoform gauze packs, chemical irritants, zinc chloride paste, tincture of iodine, cautery, and electrolysis. In my hands simple suture through the intercostal bundles has been sufficient.

The most important and often most difficult part of the operation is finding and draining the focus. Garre and Quincke write "It is difficult, often very difficult, to find the focus correctly diagnosed, when it lies low down in the lung towards the hilum or base of the lung." Tuffier, 1914, mentions a case in which nine punctures with a large trocar failed to penetrate a cavity as large as a fist, which contained 500 c.c. of pus. Tuffier, 1910, did extensive rib resections to make possible transpleural palpation of the lung. The wide open thoracotomy recommended by some French surgeons is open to the serious objections of pneumothorax, danger of infection, and difficulty in finding the lesions. Picot describes a method for holding the lobe in the wound by transfixing sutures for both exploration and incision. Robinson lays bare the adherent visceral pleura by incising the posterior rib sheath, and by establishing with the finger a plane of cleavage in the thickened pleura.

Exploratory puncture with an aspirating needle seems the safest and most accurate method of localizing the abscess. It is important in this connection to remember that the pus is most apt to lie in the parenchyma. In 30 postmortem cases at the Massachusetts General Hospital the abscess was at or near the periphery in 28 (Lord, 1909). The danger of piercing a large vessel by directing the needle deeply or by using a very large one must be recognized. In several cases in my series hemoptysis occurred, in two with temporary but alarming dyspnea and cyanosis.

If pus is aspirated, cautery incision along the tract of the needle burning a funnel shaped path furnishes adequate exposure for the search for secondary pockets after the cavity is reached and for drainage. If the cautery is kept at a dull red heat good hemostasis is also secured. Occasionally no pus but only air is aspirated. Willy Meyer considers this significant of the entry into the abcess cavity provided the aspirating apparatus is tight. In my experience air has been aspirated apparently from the bronchi.

If no pus is aspirated, burrowing into the dense area with a blunt instrument or with the finger is recommended. In one such case, after repeated negative aspirations I incised the dense area with the cautery. Even though no pus was encountered the patient made a strikingly rapid and complete recovery. In a similar case no marked improvement followed two cauterizations. The patient died suddenly after an acute hemorrhage three weeks after the operation. Necropsy showed an aneurysmal vessel burst into the cavity. The cautery had failed to reach the abscess by less than half an inch.

Garré and Quincke strongly recommend careful investigation of the cavity for secondary cavities. Körte inspects the cavity with a cystoscope.

A gauze pack is probably the best safeguard against hemorrhage for the first few days. In the presence of wide incisions drainage is comparatively simple. A rubber tube inside the gauze pack for the first few days followed by rubber tissue drains has been found very satisfactory.

The findings at operation in the fifty-four operated cases herein reported may be seen in Tables XI, XII and XIII. Pleural adhesions were firm and extensive in only about 50 per cent. of the cases. Such adhesions were present in only two of the seven cases of bronchiectasis. Primary drainage operation was performed in five instances in which there were no firm adhesions. One of the patients died of empyema. In eleven instances in which the abscess was drained in one stage the pleural cavity was opened. Three of the patients died of empyema.

The abscess was located in the right lung in 74.5 per cent. of the cases. The right lower lobe was involved in about 50 per cent. The cavities were multiple in 23.4 per cent. of the cases.

Table XII.—Operative Findings in Seventeen Cases of Chronic Abscess.

No.	Anesthetic.	Location of Abscess.	Pleural Adhesions.	Primary Drainage.	Pleural Cavity Opened.	Pus Found	Hemorrhage	Cavities.	End Results.	Necropsy Findings.
36094	Ether	Right lower	No	No	No	No	Yes	.....	Not improved.	
36479	Local	Right lower	Yes	Yes		Yes	No	..	Died in 1 week.	Drained abscess.
41553	Local	Left lower	Yes	No	No	No	No	...	Not known	
56674	Local	Right lower	No	No	No	No	No		Not improved.	
57500	Ether	Left lower	Yes	Yes	. .	Yes	No	Single	Died 1 day after operation.	Abscess, embolus, old empyema, tuberculosis.
74091	Ether	Left lower	Yes	Yes	No	Yes	No	Multiple	Died in 5 months.	None.
100299	Ether	Right lower	Slight	No	No	Yes	No	Single	Improved.	
114711	Ether	Right lower	Yes	Yes	No	Yes	No	Single	Improved (chronic bronchitis).	
116593	Ether	Right middle	No	No	. .	Yes	No	Multiple	Died 4 months after operation.	Abscess, empyema, pericarditis, pneumonia.
163709	Ether	Right lower	Yes	Yes	No	Yes	No	Single	Improved. Fistula.	
193201	Ether	Right upper	Yes	Yes	No	Yes	No	Multiple	Improved. Fistula 7 months.	
195209	Ether	Right upper	No	No	Yes	No	Slight	Single	Died 4 days after operation.	Abscess, emphysema, bronchopneumonia.
207626	Ether	Right middle	Yes	Yes	Yes	Yes	No	Single	Died 10 days after operation.	Abscess, left empyema, emphysema.
213924	Ether	Left lower	No	No	Yes	Yes	No	Multiple	Improved. Fistula 14 months.	
235549	Cocaine	Left upper	Yes	Yes	No	Yes	No	Single	Recovery.	
239564	Cocaine	Right lower	No	No	No	Yes	No	Multiple	Died 3 months after operation.	Huge abscess.
250153	Cocaine	Right middle	No	No	Yes	Yes	No	Multiple	Died 7 weeks after first operation.	Multilocular abscess. Hemorrhage.

Table XIII.—Operative Findings in Seven Cases of Bronchiectasis.

No.	Anesthetic.	Location of Lesion.	Pleural Adhesions.	Primary Drainage.	Pleural Cavity Opened.	Pus Found.	Hemorrhage.	End Results.	Post Mortem.
48566	.....	Right lower	Yes	Yes	No	Yes	No	Improved?	
80279	.....	Right lower	No	No	Yes	Yes	No	Marked improvement. Fistula.	
85333	Ether	Left lower	Yes	Yes	No	Yes	No	Suicide.	Left bronchiectasis. Old tuberculosis right apex.
98902	Ether	Right lower	No	Yes	Yes	Yes	No	Still draining 3½ years after operation.	
124560	Ether	Left lower	Yes	Yes	No	Yes	No	Died 1½ months after operation.	Chronic saccular bronchiectasis Left lung completely destroyed.
202460	Ether	Right lower	No	Yes	Yes	Yes	No	Improved; chronic sinus. Plastic operation.	
218928	Cocaine and ether	Right lower	No	No	Yes	Yes	No	Improved; draining sinus.	

In nine instances pus was not found at operation. Five of the patients died. Secondary operation was performed eight times. One patient operated on four times ultimately recovered. The important post operative incidents are tabulated in Table XIV.

Table XIV.—Post-Operative Incidents.

	Cases.	Fatal.
Hemorrhage	7	2
Empyema	6	6
Secondary abscess	3	1
Hemiplegia	2	2
Massive gangrene	1	1
Pulmonary embolus	1	1
Extensive emphysema	1	1
Convulsions	1	
Temporary blindness	1	
Arthritis	1	

The results of operation may be seen in Table XV. Of the 54 patients operated on twenty died. Excluding one who died before the second stage drainage operation could be done, and one suicide, the mortality is 33.3 per cent.

Table XV.—Operative Results.

1910-1919.	Cases.	Cured or Improved.	Not Improved.	Died.
Acute abscess	30	20 (66.6%)		10 (33.3%)
Chronic abscess	17	7 (41.1%)	2 (11.7%)	8 (47%)
Bronchiectasis	7	5 (71.5%)		2 (28.5%)

In 1918 seventeen patients presented themselves for treatment. All were operated on. The mortality, with the first exception just noted, was 23.5 per cent.

Table XVI. Post-Operative Sequelæ

Secondary abscesses	4 cases
Bronchial fistulæ, abscess cases:	
Spontaneous closure under 6 months	11 cases
Spontaneous closure after 6 months	2 cases
Plastic closure	1 case
Draining after 6 months	2 cases
Unknown	10 cases
Bronchiectasis cases:	
Spontaneous closure	1 case
Draining one year or more	3 cases
Unknown	1 case

Two patients died of acute hemorrhage several weeks after operation. One died following a second drainage operation for metastatic pulmonary abscess. He had previously had a gastroenterostomy for duodenal ulcer, drainage of a complicating empyema with bronchial fistula, and drainage of a large lung abscess following the empyema. One died of toxic gastroenteritis complicating a chronic abscess (first drained elsewhere) involving practically a whole lung. It was impossible to get this patient into condition for thoracoplasty.

Postoperative sequelæ are enumerated in Table 16. It may be noted that bronchial fistulæ occurred in sixteen (34 per cent.) of the abscess cases. Thirteen closed spontaneously. The case of plastic closure done about one year ago, has developed no complications from the closure.

The necropsy findings in all fatal nonoperative cases are indicated in Tables 17 and 18.

Table XVII. Post-Operative Cases of Abscess, Not Operated on for Abscess

No.	Diagnosis.	Operation.	Time of Death After Operation.	Post Mortem Findings.
73827	Hypernephroma	Nephrectomy	18 days	Abscess right lung, bronchopneumonia; chronic nephritis.
98059	Subdiaphragmatic abscess	Drainage	57 days	Abscess spleen, liver perforative; abscess of right lung.
101446	Tubo-ovarian abscess	Excision	46 days	Multiple abscess, pelvis, liver, lungs, subdiaphragmatic
125039	Duodenal ulcer	Gastroenterostomy	33 days	Multiple abscess of both lungs; bronchopneumonia.
128280	Cancer of rectum	Kraske	19 days	Multiple abscess both lowers; cancer of liver; left empyema.
136560	Cancer of lip. Drained for empyema	Block dissection	2½ months	Empyema (drained); abscess upper lobe each lung (tuberculosis both apices by x-ray); bronchiectasis.
139244	Exophthalmic goiter	Resection	13 days	Large abscess middle right.
146356	Right pyonephrosis	Nephrectomy	19 days	Bilateral metastatic abscesses
166661	Cancer of uterus	Cautery	18 days	Multiple small lung abscesses.
167134	Duodenal ulcer	Gastroenterostomy	33 days	Right empyema (drained); small right lung abscess base upper lobe.
168118	Cancer of stomach	Polya resection	40 days	Multiple small abscess of both lower lobes.
187340	Cancer esophagus	Witzel Gastroentomy	9 months	Abscess both lower lobes; sinuses between esophagus and lungs.
192133	Subdiaphragmatic abscess	Drainage	42 days	Subdiaphragmatic abscess, right empyema; large abscess right lung.
208921	Cancer of sigmoid	First stage. Mikulicz	5 days	Multiple bilateral abscess; bronchopneumonia.
232995	Cancer of stomach	Ant. Polya resection	22 days	Gangrene anterior upper lobes.
235339	Double nephrolithiasis	Nephrolithiasis, pelvic, lithotomy	14 days	Multiple abscesses; perinephritic abscess.
250653	Perforating gastric ulcer	Gastroenterostomy	1 days	Multiple bilateral abscess.

Table XVIII.—Non-operated Cases; Abscess Found at Necropsy.

No.	Diagnosis.	Findings.
74414	Chronic otitis media; cerebral abscess	Large cerebral abscess; abscess left lung.
129069	Endocarditis pyemia	Multiple lung abscesses of both lungs; endocarditis myocarditia.
132370	Facial cellulitis	Multiple bilateral abscesses of both lungs.
166081	Cardiac failure	Huge abscess of lower right. Bronchopneumonia.
166605	Tuberculosis, anemia	Multiple abscess of both lungs, tuberculosis of right lower lobe.
214322	Endometritis; peritonitis	Multiple embolic lung abscesses Thrombosis vena cava, etc.
221055	Empyema	Drained empyema; multiple abscess of right middle and lower lobes.

Summary.—1. Pulmonary suppuration is relatively more frequent than is generally recognized.

2. Suppuration occurs on a preceding inflammatory basis, or the infection is carried to the lung tissue through the bronchus, the blood stream, or by direct extension.

3. A persistent productive cough is the most characteristic symptom. The sputum is usually purulent, and often foul. Other clinical features of suppuration are present in varying frequency and degree.

4. Localized dullness to percussion and a circumscribed *x*-ray shadow are the most constant physical findings.

5. Pulmonary suppuration is probably frequently mistaken for phthisis. In 33 per cent. of the cases reported in this article symptoms were suggestive of tuberculosis.

6. Suppuration and a tuberculous infection may co-exist without anatomic or etiologic relationship.

7. The differential diagnosis between localized bronchiectasis and abscess may be impossible. Each predisposes to the other.

8. The treatment of localized suppuration is early free drainage. Prolonged expectant treatment or inefficient drainage greatly increases postoperative morbidity and mortality.

9. Local and regional anesthesia is safe and in most cases very satisfactory.

10. The abscess should be drained only through the adherent pleura or after the pleural cavity has been walled off by suture of the lung to the parietal pleura.

11. A two-stage operation allowing a few days for adhesions to form around the suture line probably is the best safeguard against empyema, which is a frequent and the most dangerous complication.

SPASTIC PARALYSIS IN CHILDREN.

By JACOB GROSSMAN, M.D.,
NEW YORK.
CHIEF OF THE ORTHOPEDIC CLINIC, LEBANON HOSPITAL; CHIEF OF THE ORTHOPEDIC CLINIC, STUYVESANT POLYCLINIC; INSTRUCTOR IN ORTHOPEDICS, NEW YORK POST GRADUATE MEDICAL SCHOOL.

We cannot deny that traumatism is an important factor in many diseases of the brain and spinal cord and that birth injuries may be responsible for the most severe lesions of the central nervous system.

Intracranial hemorrhage is one of the common results of a birth injury or of a traumatism occurring at some later period. Among causes of cerebral hemorrhage after childbirth, injuries, whooping cough, purpura, severe atrophy, and sinus thrombosis play important rôles. The symptoms in this condition resemble those of brain embolism and do not differ materially from the symptoms observed in the cerebral hemorrhage in adults.

Intrapartum hemorrhage into the meninges possesses a clinical importance which even yet is not properly appreciated. Where many infants have been examined post mortem, hemorrhages within the cranial cavity were often encountered. There is no doubt that in the majority of cases of other-

wise healthy newborn infants the blood is absorbed without producing symptoms; but in some cases the hemorrhage is of such extent that it renders life impossible. Between these extremes there must be a long series of intermediate degrees, the recogni-

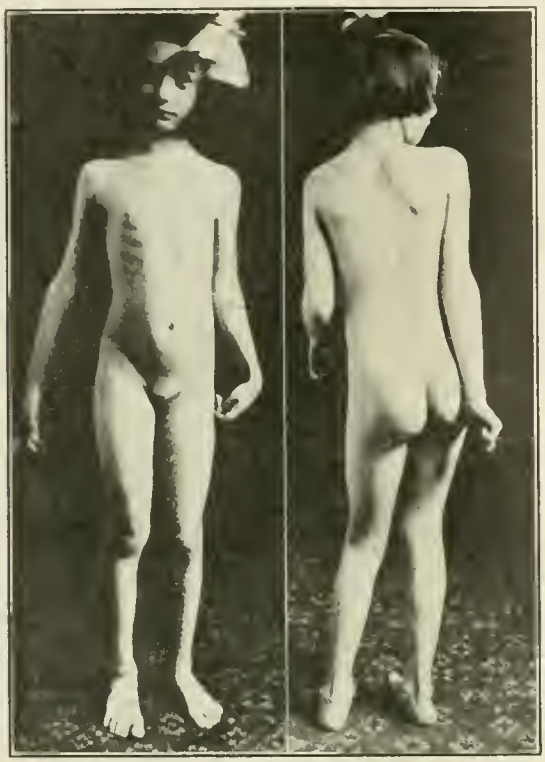

Fig. 1.—Case I. Left spastic hemiplegia occurring after measles.

tion of which is probably impossible and which no doubt are of great importance in the production of cerebral symptoms that manifest themselves later. In most cases the occurrence of congestion and laceration of the blood vessels within the skull is readily explained by a severe protracted labor with marked displacement of the cranial bones. Easy spontaneous delivery may also lead to submeningeal hemorrhage. This is particularly likely to be the case in premature labors or where there is

Fig. 2.—Case II. Cerebral diplegia.

a pathological condition of the blood or a congenital arterial predisposition.

In most of the cases the hemorrhage occurs at the vertex, somewhere in the region of the two paracentral lobules, where heavy deposits of coagulated blood have been found. The hemorrhage may involve one or both convexities of the cerebral hemispheres, more rarely the base of the brain and the cerebellum. The subjacent portions of the cortex are compressed and infiltrated with blood. In chil-

dren who have survived a hemorrhage, porencephalus, external hydrocephalus, and local meningoencephalitis have been demonstrated as end products of the lesion.

The symptoms of severe endomeningeal hemor-

Fig. 4.—Case V. Spastic paraplegia; showing equinus position of the feet.

rhage do not always point to the brain. There may be severe asphyxia; respiration may be abolished at once or may become very feeble; the child may be cyanotic and the temperature may fall. Death may ensue from gradual failure of respiration, or with

convulsions. In other cases convulsive seizures, trismus or tetanoid convulsions, spasms, exaggeration of the reflexes dominate the picture, and these cases also frequently terminate fatally. Some infants, however, survive these conditions and actually or apparently recover. In another class of cases the initial symptoms are very slight, no more than a short period of asphyxia, from which the children apparently recover completely. Later, however, convulsions make their appearance in different parts of the body, or without convulsions the children show spastic paralysis. With that degree of frequency intrapartum hemorrhage, which produces no symptoms at the time, later may lead to epilepsy or idiocy. Such an etiological relationship must be suspected whenever convulsions develop in infants several weeks of age without recognizable cause.

A number of cerebral affections in childhood, which terminate neither in complete recovery nor in death, leave behind certain anatomical defects and clinical disabilities. A permanent condition results in which the child presents certain symptoms, which represent the remains of the former disturbance. These disturbances include not only the cerebral affections in which paralysis of the extremities is the most prominent symptom, but also the numerous transitional cases, such as epilepsy, idiocy, and optic atrophy.

Etiology.—Common among the etiological factors of spastic conditions are:

1. Intrauterine (prenatal) causes: (*a*). Malformations of the brain, among which are included porencephalus, microcephalus, atrophy of one hemisphere and congenital cysts. (*b*). Cerebral diseases. (*c*). Injury to the mother, such as a severe blow on the abdomen. (*d*). Heredity and alcoholism probably have no etiological significance; the theory that emotional excitement during gestation may have an influence on the child's central nervous system is scarcely tenable.

2. Birth injuries (natal, intrapartum causes). These are chiefly intermeningeal hemorrhages which have been previously described. Even where the labors are not protracted and difficult, especially if they are precipitate, intracerebral hemorrhage is possible. Cases of cerebral palsy occurring after premature deliveries may possibly be explained in this way.

3. Among extrauterine causes, head injuries involving the skull or accompanied by subdural hemorrhage may lead to cerebral infantile palsy. Circumscribed encephalitis occurring spontaneously or during the course of an infectious disease such as measles or scarlatina, may cause cerebral infantile palsy, particularly of the unilateral variety. (See Case I.) Sinus thrombosis and embolism may produce the same clinical result.

Permanent cerebral symptoms occurring from hereditary syphilis is seen more often than was formerly believed. Case V is one in which a spastic paraplegia was present, the result of congenital syphilis.

In a large number of cases all we can learn about the beginning of the disease is that the palsy developed within the first one or two years of life, after convulsions, which in most cases are said to have been unilateral. There are many cases in which, owing to the mildness of the initial symptoms or to less observant parents, it is impossible to elicit a definite history, so that we can form no conclusion in regard to the date when the palsy began.

Symptomatology.—Infantile hemiplegia is characterized by paresis of one facial nerve and spastic weakness of the arm and leg of one side of the body. The right side is somewhat more frequently attacked than the left. The facial palsy is limited to the middle and inferior branches; it varies greatly in degree and in older cases is barely perceptible. In protracted cases of facial palsy, spasm of the paralyzed muscles is sometimes produced, so that the sound side appears smoother and the symptoms of a crossed paralysis of the extremities and face are simulated. The arm lesion often manifests itself in permanent contractures; the elbows and the wrist joints are flexed and the arm is held close to the body; fixation in extension is more rare. When the paralyses and contractures are of this pronounced type, active movements are practically impossible and the passive movements encounter a violent resistance. In other cases there is only a marked rigidity of the muscles; movements are possible, but are awkward and ineffective. The paralysis is always more marked in the hand. The fingers are folded over the thumbs and it requires considerable effort to open the hand; the finer movements of the hand are performed only with great difficulty. The legs also present a typical spastic hemiplegia, with extension at the hip and knee joints and plantar flexion at the ankle joint. Pes equinus with spasticity is often produced. Even when the paralysis is comparatively mild, the disturbance of the gait is marked; the child drags the leg and swings it around (circumduction) in bringing the foot forward. When the gait is not especially interfered with, paresis of one leg may reveal itself in the child's inability to stand alone on the affected leg, to hop, or to rise on the toes. When the child sidesteps to the sound side the paralyzed leg is dragged instead of being lifted clear, because the movement increases the spasm of the adductors. Monoplegia occurs rarely if ever in cerebral infantile palsy. There may be a greater and more evident paralysis in one or the other extremities in a given case. This is undoubtedly due to a greater degree of destruction in that area.

Paresis and spasm are therefore the characteristic features of cerebral hemiplegia. They may, however, be combined very unequally. Thus we see cases in which the rigidity of the extremities is pronounced, while the paralysis is moderate. Others again may show where the paresis and the increase in the muscle tone are marked in the leg, while the arm presents only a slight increase in the reflexes.

The deep reflexes are always increased. Ankle clonus as well as the Babinski reflex and Oppenheim's leg reflex are not infrequent. In older cases and in cases in which the hemiplegic phenomena have been less pronounced, a unilateral increase of the deep reflexes is sometimes the only visible sign of cerebral palsy. Diminution or absence of the reflexes is extremely rare and occurs only in the exceptional cases. This phenomenon has never been explained. The skin reflexes in these conditions are often diminished.

It is not rare for individual cranial nerves to be

involved in cerebral hemiplegia. The tongue may deviate toward the sound side, indicating involvement of the hypoglossus. Strabismus is quite frequent. Nystagmus, hemianopsia, a tendency to a forced position of the eyes, atrophy of the optic nerve, and ophthalmoplegia interna have also been observed.

Sensory disturbances are rare and when present are mostly confined to the hands. The disturbance of stereognosis which occasionally occurs is perhaps partly referable to the lack of digital dexterity which prevents the child from feeling objects properly.

Motor aphasia as a sequel of a left-sided cortical lesion is at times observed. In these cases the disturbance is one of speech function rather than one of pronounced aphasia.

Atrophy of the individual groups of muscles does not occur in cerebral hemiplegia. Interference with the growth of the paralyzed side is not infrequent, particularly when the palsies are acquired in early childhood or are congenital. The face may be narrow, the arm and leg may be smaller in all dimensions, the muscles and bones taking part in the atrophy. The electric irritability of the nerves and muscles in all such cases is normal or increased, which serves as an important factor in differentiating cerebral from spinal palsies.

Muscular hypertrophy occurs when the spasticity is very great and is usually due to overwork.

A peculiar phenomenon of hemiplegia is seen in the post-hemiplegic motor disturbances, which occur frequently. The mildest form is the tremor which can be seen during active movements, particularly at the height of the intended movement (intention tremor); in its severest form it may consist of permanent tremor, chorea, or athetosis. These motor disturbances make their appearance either soon after the beginning of the disease or later, following an existing spastic paralysis. The facial muscles sometimes take part in the involuntary movements. In post-hemiplegic chorea the movements are of a jerky, rotating and extending character and persist practically without interruption, except during sleep. In athetosis the characteristic movements consist in spreading, extending and flexing the fingers and frequently render the child incapable of holding an object in the hand, writing, or doing any kind of manual work. The feet may also take part in these motor disturbances.

Cerebral hemiplegia is not always strictly unilateral. In otherwise typical cases rigidity and exaggeration of reflexes in the leg which is apparently not involved, without recognizable paralysis, are frequently seen. Such cases form the connecting link between hemiplegia and diplegia. In the latter the palsy may attack either two or all four extremities. (See Case II.)

The entire muscular system may be rigid. The rigidity in these cases is noted in earliest infancy and interferes with the manipulations in bathing and dressing the child. Later delayed function is noticed in these children, of sitting and walking. There is a peculiar crossing of the legs when they attempt to walk. (See Case II.) The arms are closely pressed to the trunks and flexed at the elbows; the forearms are in pronation and flexed at the wrists and the fingers are folded. The back is rigid, the abdomen is hard and retracted, the legs are in extreme extension, the feet spastic and in a position of pes equinus. The reflexes, which are difficult to elicit on account of the impossibility of inducing relaxation, are everywhere greatly exaggerated. Oppenheim's eating reflex may sometimes be present. The children are easily frightened, especially by sudden loud noises. Strabismus and dysarthria may be present. This form of palsy is particularly likely to follow birth injuries.

Here, as in hemiplegia, there may be choreic movements, athetosis, cranial nerve symptoms, and bulbar symptoms. The choreic movements and athetosis are usually bilateral. The symptoms previously mentioned may be associated with epilepsy, dementia, or idiocy.

Course and Prognosis.—The course and prognosis of cerebral palsy are such as we should expect from the nature of the disease. Since we are dealing with a reparative process, we do not expect additional focal symptoms to develop, but rather look for the further improvement of the palsy. A great many children suffering from severe unilateral or bilateral paralysis are seen to recover. (See Case VII.) The improvement is limited; in palsies of the hand, particularly, recovery is very incomplete. The spasms and post-hemiplegic disturbances exhibit even less tendency to improvement. Occasionally the rigidity subsides and the muscular tension diminishes, while again we may see cases in which the contractures go on increasing and the usefulness of the extremities is severely and permanently impaired. The same is true of the choreic and athetoid movements, which show no tendency whatever to subside. The arms and hands suffer most in this permanent posthemiplegic condition, as all finer movements which are necessary for any kind of work appear to be interfered with. Children usually learn to walk, though it may be with great difficulty and not without resorting to many artificial aids.

Among the secondary symptoms disturbances of speech and pseudobulbar disturbances also exhibit a tendency to improve. Dysphagia also usually undergoes gradual improvement.

Sharpe, by means of a decompression and subsequent orthopedic treatment, offers relief in certain selected cases of spastic hemiplegia, paraplegia, and diplegia.

Treatment.—There is no prophylactic treatment of cerebral palsy. Cases that respond to iodides and mercury are to be suspected; they are probably brain syphilis and not cerebral palsy. The symptomatic treatment consists of massage, relaxation, electricity, exercises, and operation.

Hemiplegia.—The results of treatment depend upon the degree of mentality in the patient. From the orthopedic standpoint we attempt to stimulate the nutrition of the part, to prevent deformities and to improve the function of the affected parts.

Where the patients are seen before the secondary contractions have appeared, deformity may be influenced in great degree by massage and passive movements in the directions opposed to the habitual positions. Electricity may prove of some value. Massage and passive movements are of more value than electricity. The electric treatment must be adapted to the peculiarities of the individual case.

If the palsies are the most prominent symptoms, the faradic current is employed. The treatment must be strictly limited to the weak muscles, to the exclusion of the antagonistic muscles which are usually hypertonic. If the spasms or posthemiplegic disturbances are more prominent, sedative treatment with the anode is indicated; the anode being lightly passed over the muscles or applied to the extremity. The cathode rests on the back or upper portion of the extremity. With the massage, movements, and electricity we can improve the control of the affected limb.

In children who are old enough, and in whom the mentality is good, relaxation, as advocated by Maloney and practised by M. Grossman in spastic conditions in the adult, offers another method, the employment of which may assist us in obtaining relief of the spasticity. For the details of this method reference should be made to the recent publications of my brother, M. Grossman.

Many of our cases come to us late in childhood, when the deformities have become fixed. The foot is usually turned inward and downward; the knee is flexed and the hip is flexed and adducted. The older the deformity the greater is the resistance of the contraction. In these cases, stretching and cutting the more resistant tissues—*i. e.* the tendo Achillis, the plantar fascia and the hamstrings and the adductors of the hip usually assist us in improving function. The division of these resistant tissues and tendons should be followed by encasement of the limb in plaster of Paris bandages. After removal of the bandages a suitable brace is of service in guiding the limb. Massage, forcible passive movements, and proper exercise should be employed.

Where the arm is only slightly affected, exercises should be persisted in. In extreme cases, where the fingers are clasped over one another, treatment is of little avail. In some cases, tendon transplantation may be of assistance. Athetoid movements of the hand and arm may be relieved by prolonged fixation in plaster bandages.

Paraplegia: On account of the more marked disability and mental impairment in these cases, treatment is very much more difficult and less satisfactory. In general, in infancy, we must rely upon manipulation and massage. Multiple tenotomies with prolonged fixation may offer some relief.

It has been shown that in spastic patients the long-continued posture alone will produce permanent contractions in that muscle which is shortened by that position. It is to remove these permanent contractions that the sensitive part of the reflex arc has been resected. Excellent results are claimed for this operative procedure. It is of especial benefit in spastic conditions of the lower extremities. For the upper extremities neuroplasties have been recommended. For the hand deformities which resist all other forms of treatment, plastic operations on the median and radial nerves have been of some value.

Another operation which has benefited some cases is one in which a lateral section of the spine between the spinous and articular processes is removed, the dura opened, and the posterior roots of the lumbar and first sacral nerves are divided on the dorsal side of the ganglion.

William Sharpe, in his work on cerebral spastic paralysis, says that he has performed decompression in selected cases with gratifying results. He emphasizes that this operation should be performed only in cases showing intracranial pressure by ophthalmoscopic examination. It is of especial value in those cases of spastic paralysis with a history of difficult labor, with or without instruments, in which, on ophthalmoscopic examination, the definite signs of increased intracranial pressure are to be seen in the fundus of the eye. The operation he performs is a large subtemporal decompression to relieve the intracranial pressure. The usual pathological findings are definite subcortical fibrous or cystic formations resulting from a cortical hemorrhage occurring at birth. The aftertreatment, which consists of correction of the deformities by tendon lengthenings, or merely stretchings of the contracted muscles, or the maintenance of corrected positions through the employment of braces, massage, and faradism, should be employed in conjunction with the operation. A careful systematic course in muscle training should be carried on daily.

Case I.—Ruth L., aged nine years. Diagnosis: Left spastic hemiplegia. Family history had no bearing on the case. Personal history: Oldest of two children—the other child alive and well; breast fed; walked at one year; first tooth at six months; normal delivery. At the age of one and a half years developed an attack of measles. After this attack subsided the patient was unable to walk. On examination a right facial palsy accompanied by a paralysis of the left upper and lower extremities was elicited. Her inability to walk persisted until she was three years of age. She was brought to the orthopedic clinic of Lebanon Hospital six years later. At this time she presented a typical spastic hemiplegia. (Fig. 1, A and B.) She is receiving the routine treatment previously outlined.

In this case the hemiplegia is the result of a circumscribed encephalitis occurring during measles.

Case II.—Bessie R., aged twenty-eight months. Diagnosis: Cerebral diplegia. Family history negative. Personal history: Eight months premature; noninstrumental delivery; no convulsions at birth; first tooth at fifteen months; never sat up or walked; cannot hold her head up. She was brought to the orthopedic clinic of Lebanon Hospital at the age of twenty months. At this time she presented the picture of a typical diplegia. The entire muscular system was rigid. The arms were pressed to the trunk and flexed at the elbows; the forearms were in pronation and flexed at the wrists; the fingers were folded. The back was rigid, the abdomen was hard, the legs were in extreme extension, the feet spastic and in a position of pes equinus. The reflexes were greatly exaggerated. (Fig. 3.)

This is a well-marked case of cerebral diplegia, in which it was impossible to ascertain the etiological factor. This type of palsy is usually the result of birth injuries, as the following case illustrates.

Case III.—Baby P., aged fourteen months. Diagnosis: Cerebral diplegia. Family history negative. Personal history: First child, instrumental delivery. The child was cyanotic and did not breathe immediately after birth. Was resuscitated after a few minutes of artificial respiration. Thirty-six hours after birth the child had convulsions. The mother thereafter always noted stiffness of both arms and legs whenever she bathed or dressed the child. Could hold its head up for a short time, when it would fall forward. The child could not sit up without assistance. Never attempted to walk. When supported would walk with a peculiar gait, *i.e.* a peculiar crossing of the legs. Mentally and physically the child developed normally. He was brought to us on account of his delayed sitting up and walking. Examination revealed a well-nourished child. There was a depressed scar at the upper part of the forehead about its center. No deformities were present. There was slight rigidity of the upper extremities. The lower extremities were spastic. The knee jerks were exag-

gerated, ankle clonus was present, and there was a well-marked Babinski. There was a slight flexor contracture in both knees and hips. Occasionally the feet would be held in equinus.

This is undoubtedly a case of cerebral diplegia following a birth injury. It is a very much milder case than case II, and hence a better prognosis can be given. This child will receive massage, manipulation, and, when it is old enough, muscle training will be added.

The following case represents one in which the child was a premature one, the delivery being very rapid. No history of a birth injury was ascertainable.

CASE IV.—Charlotte K., aged thirty months. Diagnosis: Spastic paraplegia. Family history negative. One previous child. Personal history: Second child; eight months baby; noninstrumental delivery. The first eight months of this patient's life were uneventful. Occasionally the mother noticed that the child would stand on its toes and would often remark that her daughter would be a toe dancer. At the eighth month, when the child attempted to walk, the mother noticed that this toe position of the feet was more persistent. No attention was paid to this as the child had otherwise enjoyed excellent health. The mentality was good. The general nutrition was excellent. Later, when the child attempted to sit, the mother noticed that it was unable to do so. Occasionally, when it did succeed in sitting up, it did so with difficulty, and very awkwardly. This she attributed to the fact that the feet assumed an unnatural attitude. She described this attitude as one in which the toes turned inward and downward in such a manner as to throw the baby off its balance when it assume the sitting posture. This condition became progressively worse.

The patient never made any attempt to walk until she was two years of age. At this time she walked on her toes and could get around only with the aid of surrounding objects. Even with this artificial support her gait was very awkward and uncertain. This uncertainty manifested itself in the many falls which she sustained. The mother never noticed any facial paralysis. There never was any perceptible disturbance of function of the upper extremities.

When the child was first seen by me she walked with an awkward, shuffling gait. The limbs were flexed, adducted, and rotated inward. The knees touched each other. The feet were turned inward in a persistent attitude of equinovarus. The reflexes were exaggerated. Babinski was present on both sides. The mentality was good. Face and upper extremities were negative. Examination of the fundi of both eyes did not disclose any increase of intracranial pressure.

Syphilis as the etiological factor in spastic conditions in children must always be remembered. The following case is one in which the spastic paraplegia present was the result of a cerebrospinal luetic infection.

CASE V.—Henry H., aged seven years. Diagnosis: Spastic paraplegia (syphilitic). Family history: Father had a spastic hemiplegia; Wassermann four plus. Mother has a cerobrospinal syphilis; Wassermann four plus. Had had three miscarriages and four living children. All had a four-plus Wassermann. Two of these children had an eruption at the age of three months. Personal history: Third child; normal delivery. Had measles and an eruption at the age of three months; otherwise past negative. Present illness began when he was four years of age. At this time the patient had weakness of the leg muscles, stiffness, and difficulty in walking. His gait was awkard and shuffling in character. This condition progressed until he experienced great difficulty in getting around. It was at the age of seven years that this patient was seen with my brother, Dr. M. Grossman, to whom I am indebted for the report. At this time the gait was very awkward and shuffling in character. The limbs were flexed, adducted, and rotated inward. The feet were turned inward in a persistent attitude of equinovarus. The reflexes were exaggerated on both sides. Babinski present on both sides, more marked on the left. The mentality of the patient was rather sluggish. Oppenheim and fan reaction on the left side. Ankle clonus present on the left side. There were no sensory disturbances. The pupils were dilated, unequal, and fixed to light and accommodation. Wassermann was four plus. Examination of the fundi of both eyes, by Dr. S. M. Jacobs, did not reveal any signs of intracranial pressure.

In a number of cases the hemorrhage and the damage to the cerebral tissues are so severe recovery is impossible, and death occurs within a few days. The following case is representative of this type.

CASE VI.—Baby S., aged four days. Diagnosis: Left spastic hemiplegia. Family history had no bearing on the case. Personal history: First child; precipitate labor. The child was born while the mother was out of bed, the head of the child striking the floor. In rushing back to her bed, after this occurred, the mother dragged the child along the floor. The child at birth weighed seven and a half pounds. The child rested well for the first twelve hours. Thereafter it became stiff at times. There were no active convulsions. This stiffness became progressively worse. The child refused to nurse and sank rapidly, it having lost four pounds in four days. Examination on the evening of the third day revealed a poorly nourished infant, skin cold and clammy. The cry was feeble. There were no convulsions. Large hematoma over the right parietal region. The anterior fontanelle was bulging. There was marked spasticity of the left upper and lower extremities. The right side of the face was paralyzed. The reflexes were all increased on the left side. Left Babinski was present.

Operative treatment was out of the question on account of the feeble condition of the infant. Conservative measures were instituted. The infant succumbed within twelve hours. Autopsy was not permitted.

In a number of cases the hemorrhage and damage to the cerebral tissues is slight, and recovery occurs within forty-eight to seventy-two hours. One must be guarded in giving a prognosis as to ultimate paralysis, as a number of cases who at first appear to recover entirely develop signs of a spastic hemiplegia when they attain the age of twelve or fourteen months. Case VII illustrates the former type of case and case VIII the latter.

CASE VII.—Baby X., aged two days. Diagnosis: Right spastic hemiplegia. Family history had no bearing upon the condition. Personal history: First child; instrumental delivery; occiput posterior position. The labor was of twenty-four hours' duration. The child at birth was normal. It cried as soon as it was born. Thirty-six hours after birth the left side of the face was relaxed. On closer examination the right arm and leg were found to be spastic. The reflexes on this side were found to be exaggerated. Babinski was present on the right side. There were no convulsions noticeable. This condition remained stationary for about a week; thereafter it gradually began to clear up until it had entirely disappeared. The child, seen again when it was eighteen months of age, was normal.

CASE VIII.—Baby G., aged fourteen months. Diagnosis: Right spastic hemiplegia. Family history negative. Personal history: First child; full term; normal delivery. The patient remained quiet for thirty-six hours after birth, then began to have convulsive twitchings of the left eyelids, followed by spasticity of the entire body. Preceding these twitchings and spasms, the infant uttered a shrill cry. This cry lasted about thirty seconds and somewhat simulated the whoop in pertussis. Immediately thereafter the twitchings of the eyelids and the spasms occurred. The convulsions lasted about one minute and occurred periodically every half hour. During the intervals the infant was perfectly quiet. After having the convulsions for about twelve hours the patient was removed to the hospital. At this time the only physical signs present were a slight bulging of the anterior fontanelle and a slight spasticity of all extremities, more marked on the right side. The question of operation arose and, as there was

a difference of opinion, it was delayed. An exploratory lumbar puncture was performed and clear fluid under slight pressure was obtained. The bulging of the anterior fontanelle disappeared. The spasticity and the convulsions also gradually subsided, and the child had, for the present, an apparent recovery.

The child progressed very well, gaining in weight and mentality, until it was about thirteen months of age. At this time the mother noticed that the child was unable to sit up and that the right lower extremity was stiff. She also noticed occasional stiffness of the right upper extremity, especially in the hand. This stiffness of the hand manifested itself in a closing of the fingers at times so severe that it required great effort on the part of the mother to force them apart.

On examination a slight spastic condition of the right arm and leg was revealed. There was no facial paralysis. The reflexes were all increased on the right side. Babinski on the right side was present. Child was unable to sit up. It fell forward when placed in the sitting posture. There was no evidence of paralysis of the back muscles. There were no other paralyses, except as previously mentioned. The mentality of the child was good. The general condition was excellent.

Summary and Conclusions.—1. Spastic paralysis may result from an apparent normal delivery.

2. Infants who apparently recover may develop a spastic hemiplegia at a later period. A guarded prognosis should be given in all cases.

3. In a number of cases the only clue to a cerebral injury is the presence of stiffness, which mothers notice while bathing and dressing the children.

4. In other cases, delayed functions of sitting and walking direct one to the existing spastic condition.

5. Convulsions in infants, either immediately or shortly after birth, should make us suspect cerebral injury.

6. The possibility of syphilis as the etiological factor should always be borne in mind.

7. Massage, electricity, supports, tenotomies, and muscle education usually offer relief, and influence to a certain degree the existing condition.

SOME PRACTICAL HINTS ON TUBERCULIN THERAPY IN CHILDREN.

FROM THE AUTHOR'S EXPERIENCE.

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

CONSULTING PHYSICIAN TO THE MOUNTAINSIDE HOSPITAL, MONTCLAIR; CHIEF OF STAFF, MONTCLAIR FRESH AIR AND CONVALESCENT HOME.

THIS paper is offered in the hope that it may throw some light on the complex question of tuberculin therapy and may add somewhat to the working knowledge of those clinicians who are using, or who intend to use, tuberculin in their practice.

The writer entirely and unreservedly agrees with Drs. Hamman and Wolman, who say (Tuberculin in Diagnosis and Treatment, p. 241): "whatever the source from which hints, plans, or suggestions are obtained, it is the clinical data by which tuberculin therapy must stand or fall." Naturally, the more exact, thorough and well digested such data may be the more helpful they will be in the solution of the problems which confront the tuberculin therapeutist.

A few cases will be reported from the writer's practice by which it is intended to illustrate several important truths in tuberculin therapy; to wit, the frequent but unexpected benefit of small doses of the drug and the very great importance of bringing the cases under treatment at the earliest possible moment; the necessity for versatility in selecting the form and dosage of the tuberculin and in many cases, the desirability of using vaccines and different agents in conjunction with tuberculin and of employing in addition every available hygenic measure, if we wish to do full justice to our patient. And lastly, and perhaps most important of all, if we ever expect to rid the world of tuberculosis, the great truth must be impressed on everyone that we must treat the children in the so-called pretuberculous stage, or we need never expect to secure permanent and brilliant results. The cases cited in this paper are in children because, as just intimated, in them lies our hope of really making substantial progress in our war against tuberculosis, and because our knowledge of the action of tuberculin in childhood seems to lag behind our knowledge of its action in adults.

Some authorities say that the action of this agent in children does not differ from that in adults and does not need a separate description. The writer's experience leads him to maintain that children are, generally speaking, more susceptible to tuberculin than adults, and that when the results are favorable they are more quickly and more permanently manifest. The cases follow:

CASE I.—L, A., colored lad, 8 1/3 years old, school boy, 4 ft. 1½ inches tall; weight, 47½ lbs.; circumference of abdomen, 22½ inches; circumference of chest 22 inches. The family history was not important. Patient had measles four years ago. He was not very sick. Has coughed ever since up to three weeks ago when his present illness began. Now he is extremely emaciated. His belly is filled with fluid. He has no appetite. No cough or expectoration. Loud whistling, respiration sounds. Physical signs in the chest otherwise negative. He is dull and languid, takes little or no interest in his surroundings. He declines to play or to move about any more than absolutely necessary. He received, at semi-weekly intervals, eleven hypodermic injections of dilution No. 3, O. T. (1—1000). After the fourth injection he had a strong constitutional reaction. His abdomen was then softer and his color better. One injection was omitted and the tuberculin then renewed. After the sixth injection the abdominal distention was diminished, and his general condition was much improved. After the eleventh injection he seemed to be entirely well. He played with vigor and ate very well. His abdomen was apparently entirely free from fluid and was of natural size, and the child was gaining flesh. He left Montclair and has been lost sight of.

CASE II.—W. A., aged 15. Had a boggy mass in the right lower quadrant of his abdomen and suffered from fever, sweats, anorexia pain, and vomiting. A Wassermann test was negative. He responded to the subcutaneous tuberculin test. The mass in his abdomen now reached to the umbilicus. After the third injection of tuberculin this mass could no longer be felt through the abdominal wall. After the fifth injection he had gained five lbs. in weight in spite of the loss of fluid from the peritoneum. From this time he continued to improve under tuberculin treatment and has been, for the past year, in excellent health.

CASE III.—D. M., aged 7. Admitted to Fresh Air Home May 6, 1918. His previous history and family history were not fully ascertained. Weight 43 lbs. in ordinary clothes. Height 42½ inches. His admission card stated that he had tuberculous peritonitis. There was found the scar of a laparotomy and considerable water was still present in the abdomen. There were a number of enlarged glands both inquinal and cervical. The child was languid and weak. He declined to play. He was put upon tuberculin and soon began to improve. The water disappeared from the abdomen and the enlarged glands diminished in size and soon ceased to be palpable. He began to play with vigor

and even to fight with the other children in the Home. The tuberculin was continued in conjunction with nuclein until August 22, when he had a constitutional reaction. He had become sensitized to O. T. (He was then getting dilution No. 2.) Some of the constitutional symptoms from which he suffered before taking the tuberculin, viz., weakness, lassitude, anorexia, and so on, had returned. His face was pale and drawn and his color was bad, although he had gained 4¼ lbs. in weight. The tuberculin treatment was suspended and the child began to gain in every respect. His improvement continued until December when he again became languid, peevish and disposed to lie around. He would lie awake nights and cry with pain in his abdomen. The inguinal glands swelled up and were tender to the touch. He was given 0.10 c.c. No. 6 dilution of tuberculin, T. R., with nuclein. After a few injections of this form of tuberculin he was again much improved. His belly was natural to the touch and the glands were no longer palpable. About this time a few injections of pituitrin were given experimentally to ascertain whether this medicine would influence his nocturnal enuresis. No improvement in this habit was noticed; but the improvement in his general condition was so great that it seemed probable that the pituitrin had modified and reinforced the action of the tuberculin, as we know that various sera and organic extracts will do in certain cases.* The child now seems fairly well, though he is still somewhat anemic and has some indurated inguinal glands. He is now getting iron and arsenic, with daily inunctions of oleate of quinine and lard.

Case IV.—W. G., girl, 6 years old, height 47½ inches, weight 43⅝ lbs. Has lived with an active case of tuberculosis for past year. Sleeps poorly, coughs, refuses her food, is pale and cachetic. Physical examination of the lungs is negative. Subcutaneous tuberculin test applied. Patient reacted strongly and was quite sick for a day or two.

February 5, 1919, she received 0.10 c.c. No. 2 dilution of O. T. and reacted to this small dose. A change of the form of tuberculin seemed to be indicated. On February 17 and 25 she received 0.08 c.c. No. 6 dilution of tuberculin residue (T. R.), to which she reacted slightly. On March 12 she received 0.06 c.c. No. 6, T. R., with nuclein. She now sleeps and eats better. General condition better. She received four more injections from one to two weeks apart. She has gained two and one-eighth pounds in weight and is better than before taking tuberculin, although she had received since the test injections only eight injections of No. 6 (1—1,000,000), 1 of O. T., and 7 of T. R., and these at rather long intervals (one and two weeks).

Case V.—M. K., girl 19 years old, white, weighing 95¼ lbs. Patient was an eight months' baby and weighed three pounds at birth and at six months her weight was the same. Had to be carried on a pillow and suckled by a wet nurse. She did not walk until two years of age. She has, however, never been subject to colds. She has always had a voracious appetite. At two years of age she had an epileptic convulsion. These convulsions have recurred once or twice a month practically ever since. They follow slight indiscretions in diet, fright, anxiety, or overexertion and are especially apt to come on if the patient is constipated. About two months before I saw her (July 4, 1918) her appetite began to fail and her bowels were especially sluggish. She overexerted herself and got very tired, since which time she has failed perceptibly. Her menstrual periods, which had been regular since she was twelve years old, have not appeared for the past two months. Now she has been coughing and complains of a pain under the left shoulder blade. She raised some remarkably fetid sputum of a chocolate color. The pain did not trouble her when coughing but on taking a long breath. There were no tubercle bacilli in two specimens of this sputum. There was dullness on percussion posteriorly over right base. No very definite physical signs. About a month before I saw her the patient had spit up about two ounces of clotted, dark-red blood with a very foul odor. She was seen by a specialist who made no diagnosis. An *x*-ray picture of the lungs, however, revealed tuberculosis in the right middle lobe. She was put on tuberculin treatment, receiving as the initial dose 0.10 c.c. No. 6, O. T., with nuclein.

July 11, 0.12 c.c. No. 6, O. T., with nuclein. Still coughs with fetic odor to breath and to sputum. July 15 she reacted strongly to 0.14 c.c. No. 6, O. T. On July 22 she reacted again. On August 2 she was much improved in every way, no cough, no odor, good appetite, sleeps well, free from pain, menstruating after two months interval. Bowels acting well. No recent convulsions. August 18, had three convulsions. August 27, tuberculin changed to 0.10 c.c. No. 6, T. R., with nuclein given at weekly intervals. September 2, she had three convulsions in one day and the tuberculin was stopped entirely. It has not yet been renewed. On November 25, 1918, the history states that this patient has steadily improved in every respect. No epilepsy for two or three months. Eyesight better. She is now able to undertake and carry on some light employment. On December 26, she weighs 104 lbs., a gain of 8½ lbs. in 5¾ months. While her symptoms had been strongly suggestive of pulmonary abscess her subsequent history seems to disprove this diagnosis. May, '19, patient has had two or three attacks of epilepsy since December, 1918. She, however, maintains her increased weight and strength. An *x*-ray picture of her lungs shows marked improvement. She had in all eleven injections of tuberculin, all of dilution No. 6 (1—1,000,000), O. T. and T. R. While her epilepsy has not been cured, it has improved and she seems to have experienced an arrest of her tuberculosis. With good care and treatment directed largely toward bettering her digestion, her general improvement should continue as she grows older.

Case VI.—L. L., girl 9 years old, weighs 34 lbs., much emaciated, complexion fuliginous. Mucous membranes bluish. She has always been delicate. Her rectum is sore and bleeds when the thermometer is introduced. Abdomen contains considerable water. Many enlarged glands in groins. Persistent diarrhoea and at times vomiting. She reacted locally to 0.10 c.c. No. 4, O. T. She was given four injections of No. 4 and now shows decided improvement in appearance and appetite. The diarrhea has ceased. The child seemed already sensitized to O. T. and the tuberculin was changed to T. R. 0.10 c.c. No. 6. There is less ascites. After these five injections she is stronger and has red lips, bright eyes, and is more active physically, and more alert mentally. She is getting No. 6 T. R. once a week.

Case VII.—Pauline H., 9 years old, good teeth, appearance healthy. Strong and active child. All the family seem to have been healthy and vigorous. The patient had measles three years ago. She was well afterward until last November, when she was abed a week with influenza. Has been well since. In February, 1919, she began to have inflamed sclerotics and ulcers in both eyes. Those cleared up once or twice under local treatment, but promptly returned. She was given test doses of O. T. and reacted to 10 c.c. No. 2. She is now much improved after receiving eight injections of tuberculin. May 27: Eyes to gross appearance entirely well. A minute ulcer imperceptible to the unaided vision can still be detected with a lens on right cornea. No subjective symptoms noted.

We have recounted seven cases, nearly all of which showed very perceptible improvement with comparatively small, or very small doses of tuberculin.

Of the four cases of peritoneal tuberculosis, the second, third and seventh cases were brought under treatment within a few weeks of the appearance of the ascites and the improvement was prompt and gratifying; while case 4 gave us much more trouble and took much longer to recover. And this in spite of the fact that he had been removed from an unfavorable environment in the slums of a great city to a markedly salubrious one in the country, a change

*A case has recently come to my knowledge in which a patient had left a sanatorium with the understanding that he could not take tuberculin; two injections of nuclein removed his alleged constitutional antagonism to tuberculin and the patient has since received this form of medication without reaction.

in environment which is frequently of itself sufficient to arrest an ordinary case of any form of tuberculosis. I might say in passing that I have achieved excellent results in the tuberculin treatment of three cases of pulmonary tuberculosis recently that had come under treatment within a few months of the beginning of active pulmonary lesions, while cases of longer standing, although improving for a time, under tuberculin, have failed to show a permanent arrest. This important point cannot be too strongly insisted upon. We must preach incessantly to the laity and to the profession that tuberculin, like diphtheria antitoxin, must, generally speaking, be used early if it is to be of permanent benefit.

A most promising field is opening before us in the use of vaccines and lipovaccines* and other modifications of tuberculin as well as of the accessories in the form of sera, organic extracts and so on at which we have already hinted. This is too extensive a phase of the subject to receive more than a passing allusion here.

Cases Nos. IV, VI, VII illustrate the advantage which frequently follows a change in the form of the tuberculin. As clinicians we esteem it worse than useless to endeavor to reason out a *priori* what particular technique and dosage should be adopted for any patient or series of patients. I have found that there is greater difference in children regarding susceptibility to tuberculin than in adults. Hamburger showed that many children (Hamman and Wolman, p. 269), tolerated large doses easily, while in those cases cited above (cases V, VI, and VII) the patients were more susceptible to tuberculin than any adult I have treated.

As Hamman and Wolman wittingly suggest we must "keep open eyes for subtle signs" (p. 292), and we endorse without reservation their dictum that "he receives most from tuberculin who is best practised in the ordinary arts of clinical investigation and who has trained his judgment to be patient and cautious." Like John B. Murphy, we have found that tuberculin is to be used with discrimination. He said, in a letter to Dr. F. E. Stewart, "Tuberculin is one great agent we can use. I have been using it since it was introduced to the profession first in large, then in small doses, and finally I came to the 'individualization' dose. There is no average dose; there is no common dose. There is a dose for one individual and that individual alone. I become more enthusiastic over treatment by tuberculin every day."

We cannot agree with a prominent teacher who says in his textbook on tuberculosis: "But in children tuberculin is not indicated because the psychic effect, which is the main curative factor in adults, is lacking." If some years of careful study and observation have taught the writer anything definite in regard to tuberculin therapy in children they have brought him to just the opposite conclusion. He firmly believes that in the treatment of children by tuberculin and, it goes without saying, by every other approved hygienic, dietetic, and clinical method, lies our only hope of ever exterminating tuberculosis. Granted that under ideal conditions the tuberculosis with which practically all children are infected may never develop, as indeed it does not develop now in about nine children out of ten, why should we deny any of them the undoubted advantages which tuberculin therapy may convey. A negative attitude toward this proposition seems to be about as reasonable as sending a ship to sea without an anchor, because so long as the weather conditions are ideal and no accident of any kind happens, the ship may be managed very well without an anchor. It is not only our interest, it is our duty to use every available means to fight the onslaughts of the disease and to throw away our most promising agent because the average physician has not yet learned to use it properly is entirely unjustifiable. Whether a majority of the cases of frank tuberculosis will be arrested without it or not, it certainly has acted most favorably in practically every incipient case upon which I have used it.

HEADACHE AND DYSPITUITARISM IN THE LIGHT OF THERAPEUSIS.*

By JOHN A. GLASSBURG, M.D.,

NEW YORK.

CHIEF NEUROLOGIST, STUYVESANT POLYCLINIC, AND ASSISTANT NEUROLOGIST, MT. SINAI HOSPITAL, O. P. D.

Medical progress is reputably slow, but once started the strides are great. This is well shown in the advance made in the study of the pituitary body. Thirty years ago, the pituitary was considered a rudimentary organ, a vestige, a nonfunctionating cerebral appendix. In 1889 Marie[1] associated an enlarged hypophysis with acromegaly. About the same time Minkowski[2] in Berlin discovered the same relationship. Then Howell[3] in 1898 extracted an active secretion from the posterior part of the gland. Harrower[4] corroborated this work and also located the active agent in the pars intermedia. The anatomy of the gland was worked up by Swale Vincent[5] who found in it structures similar to the adrenal cortex, the islets of Langerhans, the thyroid, the thymus, and the interstitial tissues of the ovaries and testis. Schäfer[6] added to the anatomical knowledge and especially showed the great vascularity of this organ. To this was added the work of Tilney[7] in 1911, which gave a clearer insight into the minute and detailed structure. But it was Harvey Cushing[8] who, in 1910, produced his epochal study on the pituitary, who gave us the modern conception of the physiology and clinical manifestations, and it was he who first coined the term dyspituitarism to cover those conditions due to a perverted hypophyseal secretion. This term, an excellent one when the pathology of the disease is considered, should become an established diagnostic entity, and be adopted for the inclusion of both hyperituitarism and hypopituitarism, using as limitations, acromegaly on the hyperside and infantilism on the hypo side. The limits themselves should be excluded. The importance of defining and limiting the range of the term dyspituitarism, is of great therapeutic significance, for if only those cases are included which come within the suggested field, therapeusis will be beneficial. It is only these

*From the Neurological Division of the Mt. Sinai Hospital O. P. D.

middle cases which can be helped by organotherapy. When a case has gone as far as acromegaly or marked infantilism, not much can be done in the way of cure. In fact, Cushing[9] has found that organotherapy is harmful to acromegalics.

It must be understood that a case of dyspituitarism is rarely one of pure hyperpituitarism or hypopituitarism alone, but rather a combination of the two, usually in addition effecting other endocrine organs, often producing Timme's[9] polyglandular syndrome. This is best understood by reference to the pathology. Dyspituitarism is dynamic. The usual course is an initial enlargement of the anterior lobe, accompanied by the consequent signs of hyperpituitarism. The signs of the hyper stage remain, though the hypersecretion itself may cease, due to ensuing destructive changes in the enlarged gland. This degenerative process will now give rise to hypopituitarism or, according to Schäfer[10], even to apituitarism, and the signs of decreased or absent function will supercede. Therefore, we will have cases of hypopituitarism, displaying symptoms of a bygone hyperpituitarism. It is truly these dynamic conditions that should be termed dyspituitarism, and the terms hyperpituitarism and hypopituitarism be relegated to the static barriers acromegaly and infantilism.

To illustrate dystituitarism and the remarkable results obtained by treatment, I am reporting a typical case from Dr. Climenko's Clinic at the Mt. Sinai Hospital, O.P.D.

D. F., Case No. 5872.—The patient is a woman, 28 years of age, born in Russia and employed as an operator on children's dresses. Her family history shows that no one suffered from the same disease or any other special disease, though the family is of good size—four brothers and two sisters, all living and well. She does report that one sister died from puerperal eclampsia. Both of her parents are living and well.

So far as can be ascertained the patient was a normal delivery, a full term babe, no instruments used, and has always been healthy with the exception of an attack of typhoid fever at the age of ten from which she made an uneventful recovery.

The patient came to us on April 12, 1919, complaining of constant, boring, *bitemporal* headaches which had begun two years ago, drowsiness, numbness in the hands and feet, backache, muscular weakness, loss of strength, marked fatigue on slight provocation, and a rapid gain of weight, gaining 40 pounds in the last year.

She had begun to menstruate at 12 years of age, flowed four to five days at a time, was markedly irregular in her periods, sometimes flowing two days before her expected time and sometimes two to four days after her time. At times the flow was scanty, just spotting, and at other times it was copious. It is interesting to note that it was copious when the intermenstrual period was shorter and was scanty when the period was prolonged.

She has been married ten years, and during this time has had three miscarriages, the first at the sixth month, the second at the third month, and the third at the sixth month. The one occurring at the third month was self induced. The two occurring at the sixth month were spontaneous. She has never had any children.

Examination reveals a woman, 5 feet 4 inches in height, weighing 186 pounds, the adiposity being relatively well distributed. The skin is smooth, delicate, puffed, and somewhat dry, with a slight loss of elasticity. The hair on the head is very fine, silky, and abundant. The eyebrows are bushy, the eyelashes thick, and hirsuties is on the upper lip. The skin of the entire chin extending around to the ears shows scars due to the electric needle which has been employed to epilate a beard. The chest and abdomen are also covered and the pubes show the masculine vertical distribution, the hair extending to the umbilicus, forming a pyramid on the lower abdomen, instead of the usual female horizontal distribution, limited to the mons veneris. The hands and feet are small, the fingers short and stubby, the nails thin and small. The sexual apparatus is normally developed, but the patient reveals a lack of erotic emotionalism, taking no interest in intercourse, participating in the act as a marital duty. The teeth are small and the lower ones show a marked horizontal grooving, particularly of the incisors. The interdental spaces are not pronounced. The fundi are negative. There is no visual field contraction. Neurological examination is negative with the exception of a marked dermographia. Examination of the heart, lungs, and abdominal viscera reveals no abnormalities. The pulse is 60, the temperature is 98.2 , and the blood pressure: systolic 108, diastolic 96.

The urine is negative and the ingestion of 100 grams of glucose shows no sugar reaction, the urine being examined every hour for six hours. This test was repeated with 300 grams of glucose and the same result was obtained, thus showing an increased sugar tolerance. The blood examination shows: Hemoglobin 72, red blood corpuscles 4,080,000, white blood corpuscles 6,400, differential: polymorphs 63, small mononuclears 30, large mononuclears 5, and eosinophiles 2. The Wassermann is negative.

Stereoscopic radiographs of the skull show the sella turcica to be of normal size and outline. The clinoid processes are also normal. There is no evidence of intracranial pressure and the frontal sinuses appear normal.

In summary, the case presents the typical dyspituitary symptomatology—bitemporal headache, muscular weakness, drowsiness, small stature, adiposity, general hypertrichosis, male distribution of hair, disturbed menstruation, decreased sexual desire, multiple miscarriages, increased sugar tolerance, and lowered metabolism shown by the low pulse, low temperature, low blood pressure and the underdeveloped teeth, bones, and nails.

There is, however, one point worthy of comment and that is the radiographic finding. Most of the cases reported show either an enlarged or a small sella turcica. Recently Pardee[11] reported seven cases of pituitary headaches, but all of these showed abnormal sellæ. Pincherle[12] reported four cases of pituitary polyuria which responded to treatment, three of these cases had abnormal sellæ, but one had a normal sella. The one with the normal sella responded more readily to treatment. Fearnside[13] also reported a case with a normal sella. It is, therefore, important to note that pituitary disturbances may exist with normal sellæ, and, perhaps, that these cases respond more readily to treatment.

The treatment of dyspituitarism is specific and the specific is the pituitary gland. Cobb[14] uses in addition the extracts of other endocrine organs. Maranon and Rosique[15] report a case of a bullet wound in the midfrontal region which developed Frolich's infantilism and was greatly benefited by the injection of pituitary extract. Beck[16] reports four cases of hypophyseal disturbances, and in addition a large number of hypothyroid cases, 20 per cent of which showed hypopituitarism, and nearly all of which showed hypovarianism. He employed with successful results hormotone, which contains all three substances—pituitary, thyroid, and ovarian. Harrower[17] got excellent results by the use of thyroid, corpora lutea, and pituitary, singly or in combination, depending on whether the symptoms were due to the disturbance of one of these glands or all of these glands. Pardee got excellent results in his seven cases of pituitary headaches, using pituitary extract alone.

The dosage of pituitary extract is an individual

problem. There is no ordinary average dose. Some patients will thrive on 1 grain daily while others may need 300, as in one of Cushing's cases. Cushing" proposed that the rational dose "be determined by giving the individual daily an amount of glucose sufficient to produce a temporary mellituria in a normal individual of equal body weight; meanwhile an increasing amount of the extract is administered daily, until under the condition of the increased carbohydrate toleration which the patient develops, hyperglycemia occurs with a trace of sugar in the urine." This method is rather too complicated for ordinary clinical use, and the best way is to begin with a small dose, increasing gradually, meanwhile using as a guide the increase in blood pressure.

In our own case we began with 4 grains of the pituitary extract daily, by mouth; we increased this to 6 grains, and finally to 8 grains. This last dose seems to have been sufficiently large. Within two weeks the headache stopped. On cessation of the extract the headache reappeared. On continuing the extract the headaches stopped again. It was noticed that if the pituitary extract was administered at the time of menstruation, the flow was increased, lasting 8 days. It is, therefore, advisable to discontinue or be very cautious with the administration of the extract around the molimen. Now at the end of five weeks, in addition to cessation of the headaches, the patient has not gained any more weight though on a full and unrestricted diet. Her blood pressure has risen to systolic 120, diastolic 100, her pulse is 70, she is more active, and the muscular fatigue has lessened to such a degree that, formally incapacitated, she is now back at her work.

PAROXYSMAL NASAL HYDRORRHEA BASED ON DYSPITUITARISM.

By SPENCER G. STRAUSS, A.B., M.D.,
NEW YORK.
LIEUT. M. C., U. S. NAVAL RESERVE FORCE.

THE presentation of this case is undertaken not only because of its rarity, but also to emphasize the great need of recognizing clearly endocrinologic constitutional characteristics in order to employ therapeutic means rationally in the amelioration or cure of local isolated manifestations which have no clear endocrinopathic basis.

The patient was a woman aged 34; born in America of English parents. The only outstanding feature in her family history was that her father died of dementia paralytica, but the patient was not able to state whether the underlying infection had been contracted before or after marriage; at all events the patient's blood Wassermann reaction was negative. But in this connection it is interesting to recall that some observers are prone to ascribe to the toxin of syphilis an extraordinary damaging effect on pituitary balance and reversely hold that individuals in whom we find a poorly organized pituitary mechanism are especially liable to the central nervous system manifestations of syphilis.

She had had an adenoidectomy performed when she was fourteen, but otherwise her past history was negative. Here too we find a possible factor in disturbing pituitary balance. Frequently adenoidectomy is followed by the convulsive phenomena, notably chorea and epilepsy. There seems to be ground for believing that the pituitary mechanism is involved in the etiology and course of these states. Whether or no the adenoid tissue bears a genetic relationship to the hypophysis is to-day an undecided question; but it is very possible.

The patient presented herself for examination in January, 1919. She stated that two years previously she accidentally struck her forehead on a door. She was stunned for a few moments but did not lose consciousness. Two months later, without prodrome or warning of any kind, an enormously copious nasal discharge made its appearance. The discharged material was thick, sticky, colorless mucus. It was odorless. It showed a faintly acid reaction to litmus, and at times would have an excoriating effect upon the skin of the upper lip. No sneezing accompanied this discharge. No temperature elevation took place. There was no local pain or discomfort nor any malaise. A thorough rhinological examination revealed nothing very unusual There was no sinus involvement, and except for the slightly reddened and swollen appearance of the mucosa overlying the turbinates, nothing was abnormal.

This discharge which was chiefly from the left nostril, disappeared as suddenly as it began, in six weeks, and the patient found herself as well as before. During the attack she required from ten to sixteen large sized handkerchiefs a day to absorb the discharge. These attacks returned with peculiar regularity each three months and always lasted to within a few days of six weeks.

In the physical examination certain objective and subjective symptoms were brought out, which characterized the patient as an individual who tended toward a dyspituitarism. It is just this direction toward a final classical pathological entity which I believe to be of such importance, both to the patient and to the practitioner—to the former it makes possible a speedier and more logical therapeusis, which is what he seeks; and it frees the latter from the fetters of routine procedure, and enables him to view his daily problems, fragments though they be, as part of a great biological whole.

The patient was obese, weighing 196 lbs., and was sixty-one inches tall; she said she had gained weight constantly but slowly throughout her life, since the onset of her menstruation, which took place at the age of fourteen, shortly after the operation upon her adenoids. Her diet was always moderate and never in-

cluded sweets, for which she had no desire at all. Further she never remembered having experienced thirst and consumed very little fluid. These three facts alone, immediataely point to an unusual pituitary tone. Undoubtedly there is enough evidence at hand to ascribe to the hypophosis a definite role in the development of diabetes in many of its forms. Her menses were regular, scanty, and lasted but two days. She had never, however, come into the full psychic realization of her sex, inasmuch as she had never experienced the love emotion toward any other human being. It is fair to assume that she verged on the distinctly infantile type, which is definitely a pituitary disturbance.

Her respiratory and cardiovascular symptoms showed nothing unusual or significant. The patient had at various times been treated with local applications, general therapeutic measures, and climatic changes. Two facts stood out through these treatment phases: (1) applications of adrenalin always aggravated her symptoms, and (2) the attacks ran their usual course without regard to any other form of therapy.

Certainly the recurrent attacks of nasal discharge were not ascribable directly, according to the usually recognized and accepted relationships, to any degree of dyspituitarism; but on the basis of the general constitutional picture which the patient presented, treatment was begun with small amounts of whole pituitary gland preparations and within a few days a favorable effect on the hydrorrhea was apparent. Treatment in this way was continued and the nasal flood was checked in two weeks. So, cured of her symptoms, she has remained free from further attacks for six months.

Recently Castex* has reported a similar case which was markedly improved by the use of thyroid extract. His therapy was decided upon after the discovery that "she had goiter, distinct, soft, scarcely perceptible to the touch."

The fact that two patients who presented similar symptom complexes, which responded almost specifically to entirely different agents, seems on the face of it, hopelessly confusing; but on second thought, it merely emphasizes the great need of recognizing in the physical examination of any patient, traits and tendencies which distinguish that individual on a basis of endocrinological marks from other differently organized individuals, and with that differentiation as a basis, there is often found a therapeutic pathway which otherwise would be sought for in vain.

*Castex, M. R.: Paroxysmal Nasal Hydrorrhea Due to Dysthyroidism of Syphilitic Origin. *Endocrinology*, January, 1919.

Athletic Field for the University of Paris.—As one result of the war the university is to possess a "Sports Park," sponsored by Poincaré and Clemenceau. The claim is made without submission of data that university sports originated in the University of Bordeaux, where the tradition still survives. Whether the author refers to Europe as a whole or only to France is not stated.—*Journal de médecine de Bordeaux.*

A Thermometer in the Intestine.—A case, perhaps unique, is reported in the *Journal de médecine de Bordeaux*. The patient was an old man with tuberculosis, who had also been under treatment for a severe case of grippe, during which, after rectal thermometry, the instrument vanished. The rectum was explored to no purpose. Radiography showed the presence of the object in the sigmoid. To extract it it was necessary to do laparotomy and then make a button hole in the colon. Death having occurred from grippe, autopsy showed that the intervention had been a technical success. In other cases of lost thermometer the instrument has, as far as known, been recovered through the natural passages. In future in this clinic the rectal thermometer will be introduced, mounted with a cork, which will prevent its slipping into the rectal ampulla.

Medical and Surgical Lessons of the War.

TREATMENT OF PURULENT PLEURAL EFFUSIONS.

By TH. TUFFIER, M.D.

Paris, France.

Professeur agrégé at the Faculté de Médecine; Surgeon to the Hospitals; Member of the Academy of Medicine; Inspector General of Army Hospitals.

In a former article, my colleague, Depage, and I described a mode of treatment of open pyothorax, based upon chemical disinfection of the suppurating cavity followed by closure of the operative incision of the costopleural wall. Since then numerous facts have demonstrated the efficacy of this method in closed purulent pleurisy and in post-traumatic empyema of the thorax. The present time appears opportune to publish these studies, describing the operative technique and tabulating the results in my material of 47 cases.

CLOSED THORACIC EMPYEMA.

The treatment of these cases is comprised in three stages: Pleurotomy, chemical disinfection; closure.

1. *Pleurotomy.*—The procedure varies according as we have to do with a pneumococcic purulent pleurisy or with pleural suppuration not due to the pneumococcus.

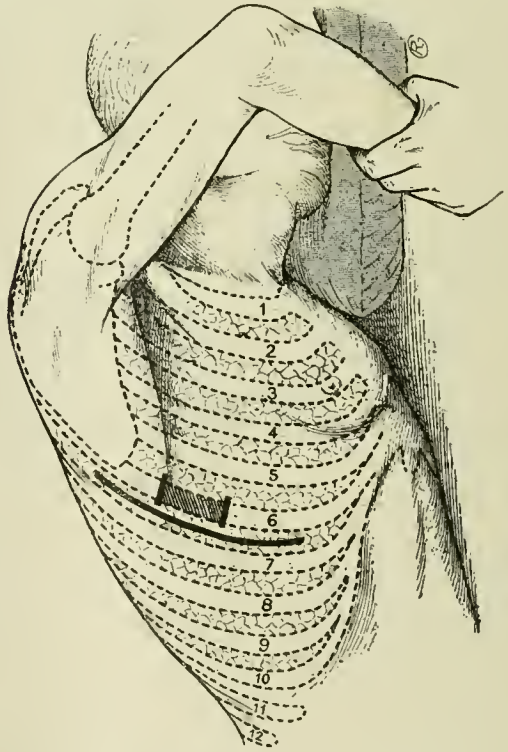

Fig. 1.—The intercostal incision, with section of a rib.

In the first case we perform a simple pleurotomy in an intercostal space. The incision is made at the most dependent point on the posterior axillary line. The separator placed in the wound shows the pleura widely open and permitting the complete evacuation of the fluid and removal of the false membrane.

In the second case (Fig. 1), thoracotomy with resection of a single rib is preferable. It allows

complete evacuation of all the pathological exudates, a wide separation of the ribs, exploration *de visu* of the entire pleural cavity, and also examination of the lung.

This exploration is important, for it shows the size, the limits, and the location of the purulent collection. Certain of the cavities are flattened transversely, others anteroposteriorly; in either of these two cases the coalescence of the two pleural surfaces will be easy, and consequently the prognosis will be better. On the other hand, we may find certain cavities having deep and irregular diverticula which we shall find difficulty in obliterating.

The examination of the lung should be made with care. The experience here related will suffice to show its importance. In examining the cavity in a case of purulent pleurisy, under a good light, I found the pleuropulmonary leaflet greatly thickened and roughened at one point. On making an incision at this point, and removing the thickened pleura, I came upon a completely isolated focus of pulmonary suppuration.

The final maneuver in this first stage is the insertion of the Carrel tubes. These tubes, to the number of seven or eight, are introduced into all the recesses, even the most distant, and in every direction, and are fastened to the skin by strips of adhesive plaster. In certain cases these tubes are armed with a mandrin of silver wire which gives them rigidity and assures their retention in the proper place. The bacteriological examination gives us information regarding the nature of the pleurisy.

2. *Chemical Sterilization.*—This is effected directly by injecting Dakin's fluid into each tube every two hours. The sterilization of the cavity is controlled by the bacteriological examination, which informs us of the nature and number of the infectious agents; it is done by taking specimens of the exudate from three points—superficial, medium, and deep—every other day. After a period of time varying from five days to thirty at the maximum, the bacteriological curve and the determination of the nature of the germs show us that the pleural cavity is sterile.

3. *Closure.*—As soon as sterilization of the wound has been obtained the surgical wound in the wall of the chest must be closed according to the technique indicated below, the greatest precaution being taken to prevent any escape of blood into the sterile cavity. The wound being closed, the pneumothorax is left to itself, and respiratory exercises will soon promote its absorption.

FISTULOUS THORACIC EMPYEMA.

In this case a purulent pleurisy has been opened into, a fistula remains, and suppuration persists. Cases of this sort, which should have disappeared from surgical practice, are still numerous. By the time the patient comes for examination the suppuration will generally be found to have existed from six weeks to a year or more, the drainage opening will be found to be small, the operative wound will be partially cicatrized, and the general condition will have become precarious.

The first thing I do is to make a microbiological examination of the pus taken from three places: (1) From the interior of the cavity, (2) from the lips of the fistula, and (3) from the skin near the opening. The nature of the purulent discharge having been ascertained, treatment is begun. This is divided into four stages: (1) Débridement and division of the pleural adhesions, if there are any, (2) chemical disinfection, (3) decortication, (4) closure of the opening through the thoracic wall.

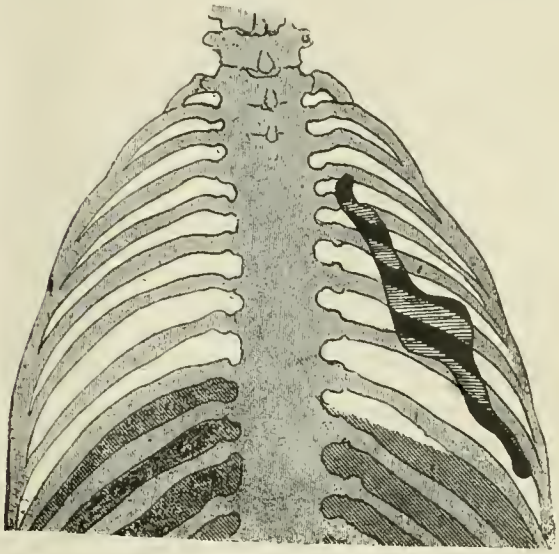

FIG. 2.—A cavity injected with bismuth.

1. *Débridement and Loosening of the Adhesions.*—I introduce through the fistula into the cavity several rubber tubes armed with silver wire to secure rigidity. A radiogram is now taken by means of which information is obtained regarding the general shape and approximate extent of the cavity. In certain cases in which the diverticula were especially numerous I have injected bismuth into the cavity, obtaining thereby very illuminating radiograms. This method brings to light certain narrow and far-reaching diverticula which might otherwise escape detection. (See Fig. 2.)

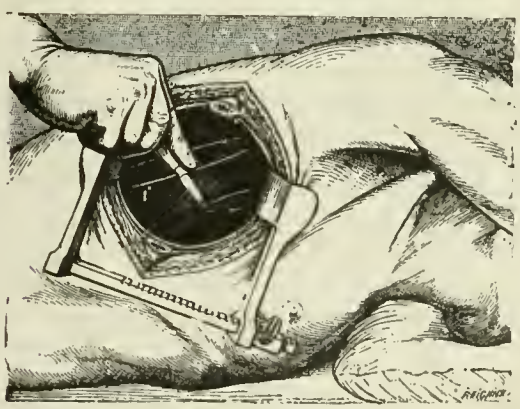

FIG. 3.—Dissecting adhesions at the bottom of the cavity; showing also the Tuffier separator.

This exploration is necessary only in those cases in which one does not wish to undertake débridement of the fistula at once. In all other cases, wide excision of the walls of the fistula should be made. This operation should be of sufficient extent to give access to all the recesses of the cavity by permitting the use of widely separated retractors. The pleural cavity is then illuminated and explored *de visu.* In this examination one most frequently finds grayish false membranes over the surface of the retracted lung. These can be removed by simply

wiping them away, and then one can note the condition of the pleural surface and determine the situation, number, and size of the diverticula and the amount of the false membrane. In view of the fact that the cavity is infected, operation therefore being dangerous, one should be content at this time to insert a series of Carrel tubes in order to permit of disinfection. If the false membrane is easily detached we may remove it at this time; and, indeed, if the cavity is sterile we may close it at once.

2. *Chemical Disinfection.*—This ought to be practised with the greatest regularity. Dakin's fluid is to be used, but unfortunately it is badly borne when bronchial fistulas are present, the injections often provoking paroxysms of coughing, which we should avoid if possible. In such cases we may have recourse to injections of oxygen, freely used every hour. During the entire course of this disinfection we should daily practise methodical pulmonary gymnastics. The size of the pleural cavity is measured by the quantity of fluid required to fill it, and the expansion of the lung is easily calculated by determining the difference in the volume of fluid retained during inspiration and expiration.

When the microbiological examination of the secretion, made every other day, gives us the assurance that clinical sterility (one microbe in four fields, or less) has been secured, we may proceed to the third stage of the treatment. Nevertheless, in order to be absolutely sure of the sterility of the pleura it is prudent to take a specimen after the cessation of the antiseptic treatment. For this purpose we remove the Carrel tubes and apply a dry compress to the wound, retaining it in place twenty-four hours. Three specimens are then taken in succession from the bottom of the wound, from its edges, and from the neighboring integument. If all three of these are negative the wound may be closed.

3. *Decortication.*—We first resect the fistulous tract, and then practise partial or total decortication. The opening through the chest wall being dilated by my separator (Fig. 3), one can see and attack the false membrane, forming a veritable pulmonary shell, at its periphery, that is to say, at the attachment of the lung to the thoracic wall. This first step is rather difficult of execution, and the opening in the chest wall ought to be sufficiently wide to facilitate this, especially toward the apex of the lung. When this separation is completed by the bistoury, a sort of lengthened spatula which I have had made for this purpose enables me to double over the layer of false membrane. The lung is seen immobilized along the pleurocostal groove (Fig. 4). The decortication of the lung may be made from without inward or by median, transverse, or longitudinal section, forming two strips (Fig. 3). In certain cases this dissection is possible throughout, and one can see the lung expanding, coming out of its shell and filling the thoracic cavity.

This decortication should remove the false membrane completely from the lung, covered with its delicate pleura, the latter being intact, so that the operation is strictly a decortication and not a pleurectomy. There may be in certain cases a slight bleeding and the escape of a few bubbles of air, which indicate that there has been a little erosion of the parenchyma. When this total decortication *en bloc* is not possible we must resort to morcellation; that is to say, pick away the pulmonary false membrane wherever it can be separated from the lung without tearing the latter, and be content with reducing its thickness in the strongly adherent parts.

If we find very close adhesions, as we may over the site of the lesion, whether traumatic or medical, of the lung, we are usually obliged to leave them alone, the intrapulmonary dissection being often dangerous. Finally, if a bronchial fistula exists, we must close it by overlapping after Lambert's method. When the pseudomembrane covering the parietal pleura is easily detached we may remove it, but if not, it may be left without any special inconvenience.

4. *Closure.*—When the operation is finished, and the surface, denuded of false membrane and covered with a light compress, shows no bleeding points, we may close the wound, either by two tiers of sutures, the deep one of catgut, the superficial of horsehair, or in a single musculocutaneous layer, no attempt being made to restore the continuity of the pleura.

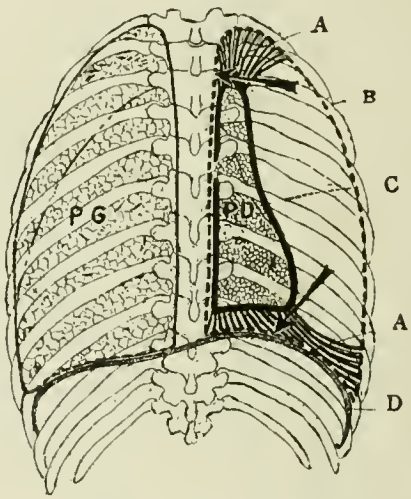

FIG. 4.—Periphery of the cavity to which the incision should be carried; AA, adhesions; B, parietal pleura; C, pulmonary pleura; D, diaphragm.

When there is a rather profuse oozing of blood, the suture should not be complete. A thin layer of gauze is laid over the surface of the lung so as to absorb and remove the blood, and then the wound is partially closed. The following morning the gauze is removed, the stitches previously inserted at the pleuroparietal opening are tightened, and closure is then complete.

This decortication technique is, in the main, that of Delorme. The reason why it was so rarely successful formerly is that we used to operate in a septic milieu, which resulted in a return of the pleural suppuration and of the pseudomembrane. Now, the operation being performed under septic conditions, we can leave the pneumothorax to itself, and it is soon absorbed, the lung coming back into its place.

This membranous shell being often infected throughout its entire thickness, I believe we could improve the technique by removing it before the disinfection of the cavity is completed.

The only postoperative complications that I have

encountered are (1) the occurrence of a new septic exudation, usually of slight extent, which, however, called for reopening and sterilizing, and (2) a breaking down of the superficial portion of the cicatrix, the result of an osteitis at the end of the resected rib. A delay in the final cure is the only inconvenience resulting from these complications.

The surgical tendency at the present day is exactly the reverse of that which formerly prevailed; it is no longer the thoracic cage which demands precedence of the lung, but the lung which is always to be considered before the chest wall. The advantages are considerable for the future of the patient; the lung regains its normal functioning, whereas under the old methods everything conspired to prevent it.

STATISTICS.

Up to June 1, 1919, I had operated in 47 cases, of which 7 were cases of medical empyema and 40 were purulent pleurisy consecutive to wounds of the lung. Of these 40 cases, 3 were recent and 37 chronic; all were cured except one chronic case.

Medical Empyema.—At the time of operation the disease dated back two weeks in two cases, a month and a half in one case, two months and a half in one case, four months in two cases, and three years and a half in one case.

The time required for sterilization was ten days in two cases, seventeen days in two cases, one month in two cases, and four months in one case (the one which had lasted three and a half years).

The closure of the wound was effected in two cases ten days after the operation, two months and four months respectively after the beginning of the disease; in two cases seventeen days after the operation, one month and two months respectively after the beginning of the disease; in two cases one month after the operation, three and a half months and five months after the beginning of the disease.

The microscopic examinations showed the presence of staphylococci, streptococci, and diplococci in five cases, of streptococci alone in two cases.

Purulent Pleurisy Following Wounds.—At the time of examination the wound dated back three weeks in five cases, a few days over a month in seven cases, two months and some days in nine cases; three months in six cases, four months in five cases, five months in four cases, seven months in two cases, eight months in one case, and one year in one case.

The chemical sterilization required two weeks in eight cases, these dating back from three weeks to one year; one month and some days in fifteen cases, dating back from three weeks to eight months; a few days over two months in seven cases, dating back from one to three months; three months in one case, dating back one month; four months in two cases dating back two and seven months respectively; and six months in one case dating back three months. In one case in which closure was effected on the same day as the operation, there was no sterilization. In three cases a recurrence occurred, but sterilization was again effected and the cases were cured. In two cases there was no record of the time required for sterilization.

Closure was effected in seven cases in a fortnight after operation, one to six months after the receipt of the wound; in fifteen cases one month and some days after the operation, from a month and a half to a year after the wound; in eight cases two months after the operation, from two to ten months after the wound; in one case three months after the operation, five months after the wound; in one case four months after the operation, four months and a few days after the wound; in one case six months after the operation, one year after the wound; in two cases seven months after the operation, eleven months after the wound; and in one case nine months after the operation, eleven months after the wound. In one case the patient was evacuated with a small fistula seven months after the operation, eleven months after the wound. In three cases there was no record of the date of closure.

The microscopical examination showed in twenty-six cases, staphylococci, diplococci, and streptococci; in one ase the perfringens, anaerobes, staphylococci, and the vibrion septique; in four cases pneumococci and Friedlander's bacillus; in nine cases no record was made.

The following complications occurred: In eleven cases it was necessary to reopen the wound because of a recurrence of the purulent collection; in two cases the wound had to be reopened twice. All these patients were eventually cured. In two other cases the wound was reopened—one on account of a fistula leading to bone, the other because of hemoptysis.

The notes mention a slight deformity of the thorax in nine cases, and one quite marked deformity in a case coming under observation seven months after receipt of the wounds.

The respiratory capacity was mentioned in four cases; it was from two to three liters by the spirometer.

Medicolegal Notes.

Proximity of Pesthouse.—The Oklahoma Supreme Court holds that depreciation of the value of real property caused by establishing a hospital for contagious diseases, commonly known as a pesthouse, on adjacent land, although under statutory authority, constitutes a damaging of private property for public use, for which compensation must be made, within the meaning of section 24, art. 2 of the Oklahoma Constitution. The fact that the city, in erecting and operating such a hospital, was exercising a lawful governmental function, did not warrant its exercise in violation of the constitutional guarantee to the citizen that private property should not be damaged for public use without just compensation.—Oklahoma City v. Vetter, (Okla.) 179 Pac. 473.

The federal district court for the Eastern District of New York holds that section 8 of the Harrison Narcotic Act, making it unlawful for any person who has not registered and paid the special tax to have in his possession any of the drugs named, applies only to the classes of persons required by the act to register and pay the tax. It holds that the act is constitutional except so far as section 8 is concerned.—United States v. Denker, 255 Fed. 339.

Weight of Expert Opinion.—While the testimony of medical men of large experience in their profession of soundness or unsoundness of mind is entitled to consideration by the jury, they are entitled to consider whether the doctors who have testified were in fact men of such large experience as to entitle their testimony to more weight than the evidence laid before the jury. The weight to be placed upon all the opinion evidence of any kind, doctors or laymen, is for the jury to determine.—In re King's Will, 172 N. Y. Supp. 873.

THE DANGERS OF LUMBAR PUNCTURE.

THE frequency with which the cerebrospinal liquid is withdrawn for examination has increased greatly within the last few years. This is due in part to the well-established belief that the procedure of lumbar puncture is practically without danger to the patient and that the material obtained may yield information of great value. Certain contraindications have been recognized, but they are few. But recently certain studies carried on in the investigation of meningitis have shown that there may be a very serious danger indeed connected with this apparently simple operation. Wegeforth and his associates found that the release of cerebrospinal fluid during certain artificial septicemias in animals is followed by a localization of the infection within the meninges. The application of this observation is immediately obvious and study of the human patient was begun.

Wegeforth and Latham have recently presented the results of this study and their conclusions as to how the undesired consequences may be avoided (*Am. Jour. Med. Sci.*, 1919, clviii, 183). They have been able to observe several cases in which the blood showed the presence of a meningococcus or a pneumococcus and a lumbar puncture released fluid that was normal or at the most showed a slight increase in the cell content. But following the puncture the patient developed a typical acute meningitis. It is true that this result was not an invariable one, but in those instances in which the meninges escaped infection there was generally evidence that the infecting agent was of diminished virulence. Also, meningitis did not occur if the puncture was made after the patient had received antimeningococcus serum intravenously. The clear warning for the clinician in these observations is to avoid lumbar puncture, so far as may be possible, in those patients who have a positive blood culture. It should be remembered that with a meningitis due to any other organism than the meningococcus, the demonstration of a purulent, bacteria-containing fluid is of but slight value and the patient had better, therefore, be left alone. With the meningococcus in the blood, the necessity for the introduction of serum into the subdural space is a pressing one, if there are any symptoms of meningeal irritation and the puncture seems unavoidable. The authors urge that if a puncture must be made under these conditions, a very small needle be used and the smallest possible amount of fluid be withdrawn. In the absence of acute infection, the above restrictions, naturally, have no force. It is significant to note that within twenty-four hours, or even less, after the withdrawal of a fluid which is practically normal, the meninges may exhibit the lesions of a severe general inflammation and the fluid contain abundant pus.

THE IMPORTANCE OF SYMPTOMS.

OF late years the significance of symptoms as a means of diagnosis and as a basis for treatment has been largely disregarded. Perhaps, this indifference to symptoms manifested by the up-to-date physician is chiefly due to reaction. There was a time when diagnosis was of necessity wholly guided by symptoms, and, in fact, so far as treatment was concerned, these were, for the most part, the points considered. Then dissatisfaction arose as to results, and it was clamorously declared that correct diagnoses were the exception rather than the rule and that this was owing to the importance paid to symptoms. Of late the shoe has been on the other foot, the modern physician in his efforts to make a correct diagnosis has waived aside symptoms, that is, has not allowed himself to be unduly influenced by them, but has relied largely upon the laboratory findings in his efforts to discover the real nature of the disease.

But now appear signs that the pendulum is beginning to swing back and men are asking if these highly scientific methods are as infallible as their high priests would have us believe, and whether diagnosis and the treatment based upon it are so much more successful than in bygone times. Sir James Mackenzie, who certainly cannot be termed an unscientific empiricist, is one among many who are not altogether in favor of the ultra modern way of paying no attention to the clinical aspect of disease and of depending solely upon chemical and biological tests.

In the *Medical Press* of August 13, 1919, Dr. F. G. Crookshank defends the older methods and points out that a vast amount of practical wisdom, the fruit of the experience of generations, has been ruthlessly scrapped by a mentally lazy generation on that flimsiest of logical excuses, to wit, that an observation must necessarily be erroneous when it cannot be explained. Dr. Crookshank has no hesitation in saying that, in spite of the glitter of the modern specialist's ways, and of the almost incredible advances that have been made in surgical technique during the past thirty years and also in the domain of tropical medicine, it is nevertheless true that in the sphere of ordinary medical practice progress has been but slight. Finally, the author states what is obviously true, that the treatment of disease, whether of individuals or of com-

munities, should always have as its immediate objective the restoration of order in the performance of function, in other words, the removal of symptoms, and it is neglect of this treatment of the symptoms of communities that has been responsible, in great measure, for our failure in respect of the present pandemic.

Of course, it is well to know, if possible, the cause of disease in order to prevent it or treat it successfully. It is evident, too, that biological and chemical methods possess great value as a means of arriving at a correct diagnosis, but so also does observation trained by long clinical experience. The diagnostician is, to some extent, born, not made, and such a man with a long clinical training is, on the whole, more to be relied upon to make a sure diagnosis than the one who depends upon laboratory findings exclusively.

INFLUENZA SPECULATIONS.

In the *Lancet* of August 9, 1919, Dr. G. G. Beaumont gives an account of bacteriological investigations with regard to the etiology of influenza done by him first under the direction of Capt. Fry and then alone. His conclusions from these bacteriological examinations are as follows: Examination of material obtained from patients suffering from influenza has shown the presence of a mycotic organism. It is possible that the disease is a mycosis, not necessarily in all cases a bronchomycosis, but perhaps in some an enteromycosis. Beaumont goes on to say that the originality of these findings belongs to Captain Fry and that, while the results obtained do not justify an assertion that influenza is a mycotic infection, they appear to demonstrate the fact that such an organism is present during the disease and afford a means of unifying the seemingly discordant results that have been obtained by other workers.

Dr. J. D. Benjafield, in the *British Medical Journal* of the same date, records his views and those of his coworkers drawn from experience of the influenza epidemic in the Egyptian Expeditionary Force. The conclusions are as follows: (1) There is no valid reason for assuming that the primary cause of influenza in Egypt and Palestine differs from that of the recent pandemic. (2) There is no justification for regarding *Bacillus influenzæ* (Pfeiffer) as the primary cause. (3) From the work of various investigators it is more reasonable to regard both the influenza bacillus and the streptodiplococcus as secondary invaders, the former being the predominant organism in Europe, the latter in Egypt and Palestine. (4) In this case it is more than possible that the primary etiological agent is ultramicroscopic and is a filtrable virus, which renders the individual infected hypersensitive to organisms which formerly possessed a low degree of pathogenicity. Benjafield reports good results, in some cases remarkable results, from vaccine treatment of acute pulmonary cases in which streptodiplococcus was the predominant organism.

Opinions as to the etiology of influenza vary so much as to be positively discordant; but there appears to be a certain agreement on the point that streptodiplococci are very frequently found. The suggestion that both the influenza bacillus and streptodiplococcus are secondary invaders is novel, but is not unlikely to be correct. Weighing all the evidence, it seems probable that the primary cause is a filtrable virus which lowers vitality, thus rendering the subject particularly sensitive to further infection. It is also suggestive that a mycotic organism is present during the disease, but does not prove that the malady is a mycosis, although that is possible. Moreover, the pleomorphic coccus isolated by Donaldson and described by him in the *Lancet* of November 23, 1918, may be the actual causative agent in influenza, albeit evidence in this direction is as yet incomplete.

Filtrable Virus.

Sampietro contributes a long article on the subject to the *Policlinico* for July 6. He concludes that up to the present moment we have no exact or definite knowledge of the nature or mechanism of action of the substances comprised under the heading filtrable viruses. There have been contentions which appeared to give a practical status to the latter, but they have all been shown to be based on fallacies. There is, however, a great body of accumulated facts which bear on the subject, and there is good reason for believing in a definite relationship between these substances and the so-called cellular inclusions. Some of the viruses no doubt play a rôle in the life cycle of the protozoa and protophyta. In addition to hypothetical amorphous virus, there are also forms of bacteria which are able to traverse the filter. Certain microorganisms of the ordinary size probably act as hosts to smaller and filtrable germs. One startling property of the filtrable virus is its extreme diffusibility, which is responsible for the existence of great pestilences, in fact, for the majority of them. But few of these have been traced definitely to an organism of appreciable size, and more than one bacteriologist has come to look upon all organisms of measureable size as able to cause only secondary infections. Eberth's bacillus, for example, has been regarded from this viewpoint. In animal pathology even more than in human pathology do we find those associations of filtrable and sensible organisms which are necessary for the production of the clinical picture of the disease. The filtrable viruses per se do not appear to cause severe affections in the absence of the sensible organisms.

Oligodynamic Action of Copper.

Many years ago the Swiss botanist Naegeli made the discovery that certain algæ could be poisoned by mere contact with metallic copper. The amount of copper to find its way into the water which contained the algæ was truly minute. The poisonous action thus exerted was assumed to be something different from the toxic action of the drug in sensible amounts. Since that period many peculiar phenomena have been studied in connection with

salts of copper. The latter metal under certain circumstances appears to dissolve because certain soluble salts have formed. To cite one of many examples, milk will dissolve the copper in a container in the presence of hydrogen peroxide. This problem touches upon another—the alleged toxicity of the metal in preserving tins under certain circumstances. We have to consider in this connection the law of subdivision in solutions, the phenomenon of adsorption and the laws of chemical combination, including the action of catalysts. A familiar phenomenon is the socalled Pagenstecher reaction. Here the addition of prussic acid to a solution of a copper salt, even in the most minute quantities, will oxidize guaiac resin as indicated by the appearance of a blue color. The reaction, which resembles that due to enzyme action, has no such nature. A biological reaction is as follows: a certain species of crab is poisoned by distilled water, but if salt is added the toxicity is abolished. If the experiment is tried in both glass and copper vessels four times more salt is required as an antidote in the latter. Hence a minimal amount of copper goes into solution which forms with the chloride some complex mixture. This is possible because the copper is first ionized after which it forms bodies with the salt in solution. As a result, the copper loses its toxicity. In the Pagenstecher reaction two reducing substances come together and the result is an oxidation of the guaiac resin. Haussmann, writing on this subject in the *Correspondenz-Blatt für Schweizer Aerzte* for July 3, claims that this and similar phenomena involve no new principles, but can be explained by laws of chemistry and chemical physics already known.

Some Experiences with the Finnish Influenza Epidemic of March-April, 1919.

Under this title, which appears in the *Finska Läkaresällskapets Handlingar* for May-June, an epidemic phase of the pandemic without a counterpart perhaps in other countries is described at length. It will be noted that this period is too late for an outbreak of ordinary winter grippe and hence it suggests a return appearance of the pandemic of 1918. During the preceding summer and fall there had been a wave of the pandemic in Helsingfors. The outbreak in March was preceded by the appearance of sporadic cases. During March and April over 8,000 subjects were attacked in Helsingfors. The number of admissions to the Maria Hospital was over 400. The death-rate for this material was over 30 per cent. and that of the males alone 39 per cent.; men who developed pneumonia showed a mortality of over 50 per cent. While many more women than men were attacked by this wave of the pandemic the mortality among the men was much higher. Elsewhere we find the statement that in the first outbreak the number of hospital pneumonia cases was 310 with 123 deaths, a mortality percentage of about 40. Hence the second outbreak was at least as severe as the first, and apparently did its fell work in a much shorter time. The possibility of winter grippe was at once excluded by the death rate. This experience in Finland gives us some idea of return epidemics. So far as known the interval is relatively brief, not over 3 months. Many countries have had their second wave, while others, like our own, seem thus far to have escaped recurrence. The author neglects to mention the subject of immunity in the second wave.

The Therapeutic Value of the Oculocardiac Reflex.

Introduced originally as a diagnostic resource, Voisin and Benhamou have obtained encouraging results from this reflex in therapeutics (*Journal de médecine et de chirurgie pratiques* for July 10). Thus in nervousness expressed as paroxysmal tachycardia, when essential, and even in the permanent form, transitory improvement has been obtained and even in some cases a certain degree of permanence. The provocation of the reflex has slowed the heart, a fact perceived by the patient himself, who moreover has also at times experienced a sense of calm and well being and of relief from oppression. Since some of these patients are really subject to a neurosis of cardiac expression the cure may be essentially psychotherapeutic. That this is so is shown by the fact that cures have been obtained in psychogenic maladies in which heart symptoms are absent. Among such cases have been tremor and epileptiform convulsions. It is possible that these good results were not due to any complicated mental suggestion but merely to diversion of the patient from his malady.

News of the Week.

Typhus in Europe.—Mr. Henry P. Davidson reports that 275,000 cases of typhus fever have been found in the belt extending from the Baltic to the Black Sea and that there is appalling distress in Poland, Lithuania, and the Balkans. The Red Cross has sent 200 representatives to Poland in response to an appeal from Paderewski. Edicts calculated to stop the spread of the disease in that country have been published, one of them being that every person shave and bathe.

Red Cross Activities in France.—The American Red Cross has recently made public a brief survey of some of the activities in which it is still engaged in France. The Maternal Welfare Work established in France, under the auspices of the Red Cross Children's Bureau, by Dr. F. L. Adair of Minneapolis, is to continue. The plan of prenatal consultation established by Dr. Adair is to serve as a model in the School of Puericulture of Child Welfare, and is to function under the American Red Cross Children's Bureau cooperating with the Medical College of Paris. In the few months during which the work was carried on in two sections of Paris having a population of 600,000, about 500 prospective mothers were cared for in the consultations and in their homes. In the hospital Social Service work, which was conducted for only two months, over 500 prospective mothers were interviewed. It is said that the response of the people to this work is most pathetic showing how great is their need of guidance. The activities of the Red Cross in combating tuberculosis are also being maintained. Through the agency of this organization there is now a

capacity for 1983 bed patients in the tuberculosis hospitals in Paris and outside of Paris there are accommodations for 5610. The Bureau of Tuberculosis of the Red Cross is working in close cooperation with the Rockefeller Commission for the Prevention of Tuberculosis in France. The total number of beds assisted by the Red Cross Bureau of Tuberculosis amounts to 24,185, aid having been given to the extent of 3,287,417 francs. An appropriation for a Serbian Hospital in France has been made because it was found, after examination, that 20 per cent. of the 200,000 Serbs studying in France were tuberculous. Canteen schools have been established in many French cities by the American Red Cross. This innovation was first begun at Lille, where hundreds of refugees were passing through and practically all the children were undernourished. At these schools the children were given the kind of nourishment they needed. Public health nurses and doctors have been sent to the schools by the Red Cross and more than 19,000 children have been examined by them. Every doctor and nurse who took part in the examinations received a letter of thanks from the Mayor of Lille.

Films to Aid Health Drive.—An educational propaganda, through the use of motion pictures by means of which various matters pertaining to housing, health, and industry, food, the control of the milk supply, and similar topics, has been undertaken by the New York State Reconstruction Commission. It has been arranged to send a number of motor trucks mounted with picture machines into every section of the State within the next two months.

Post-Graduate Course for Public Health Nurses.—A post-graduate course for public health nurses is to be given in Buffalo for sixteen weeks beginning September 29, under the auspices of the Buffalo University, the Buffalo Chapter of the American Red Cross, the Department of Health, the District Nursing Association, and the Department of Hospitals and Dispensaries. A certificate will be given to all students satisfactorily completing the course, which will cost $25. The class will be limited to thirty students. Application blanks will be supplied by the University of Buffalo, College of Arts and Sciences, Niagara Square, Buffalo, N. Y.

Positions Offered to German Surgeons.—According to a despatch to the Associated Press, the medical journals in Germany are publishing advertisements offering positions to German physicians and surgeons in the Russian army. Medical men are urged to enlist with volunteer troop units organized for fighting Bolshevism and the promise is made of a premium of 5,000 marks if the counter revolution is successful.

Red Cross Sends Aid to Minsk.—The American Red Cross, as a result of the capture of Minsk by the Polish Army, has despatched a general relief and antityphus field unit to that city. Reports from Minsk are that people are dying in large numbers from hunger and typhus, while among children there is much disease, particularly trachoma. The Red Cross unit will include two American health experts, a chief nurse, and about fifteen Polish-speaking nurses. They will carry with them supplies of medicines and nourishing foods, and one of their first undertakings will be the establishment of a diet kitchen in Minsk.

More Yellow Fever in Nicaragua.—According to a report recently received from San Salvador, a number of new cases of yellow fever have developed at Corinto, Nicaragua, and Amapala, Honduras, and a number of fatalities have resulted.

New Case of Leprosy Found in New York.—A man, 23 years of age, was recently removed from a boarding house in Manhattan to the Department of Health's Reception Hospital, suffering from leprosy. He presented the typical appearance of the mixed type of the disease, ulcerated-tubercular, and is the kind of a case requiring isolation. At the present time, according to the records of the Health Department, there are 29 cases of leprosy in New York, 13 of which are under quarantine.

Few Sick Babies in New York.—Reports reaching the Bureau of Child Hygiene of the New York City Department of Health from the various Baby Health Stations and from the district nurses in the field indicate that there is a very low incidence of sick babies in the city at present. The prevailing infant mortality rate is 87, with a reduction of 506 infant deaths for the first six months of 1919. Of some 3,400 babies under observation by the district nurses in the Borough of Manhattan during the present summer, only 47 have been found ill from gastroenteritis, and eight from other causes. The Baby Health Stations report comparatively few cases of diarrheal diseases among their clientele.

To Combat Cholera in Siberia.—The prevalence of cholera in China and Siberia has caused Major General Graves, commander of the American expedition in Siberia, to request the War Department to send a special detail of medical officers to Vladivostok to combat cholera should it spread to points where it would threaten American troops. Lieutenant Colonel Eugene R. Whitmore, Captain Charles B. Spruit, and Lieutenant T. J. Crooks have been ordered to proceed immediately to San Francisco for departure to Vladivostok. At San Francisco these officers will be joined by Lieutenant Colonel James G. Cumming.

Dr. Morton Prince of Boston has been decorated with the Cross of the French Legion of Honor by Dr. Marcel Knecht of the French High Commission for his services in promoting Franco-American cooperation during the war.

Dr. John F. W. Meagher, who has been absent for two years with the army, has resumed his practice at 220 Brooklyn Avenue, Brooklyn, N. Y.

Dr. Emil Goetsch, formerly full-time associate professor of surgery in Johns Hospkins University and associate surgeon in Johns Hopkins Hospital, has been appointed professor of surgery at the Long Island College Hospital, Brooklyn, N. Y.

Miss Clara Noyes, acting director of the Department of Nursing of the American Red Cross, has been decorated with the Patriotic Service Medal of the American Social Science Association and the Council of the National Institute of Social Science, in recognition of the inestimable service she rendered her country and its wounded.

New York Drug Clerks Threaten to Strike.—The

United Drug Clerks of New York recently held a meeting at which they ratified resolutions demanding higher salaries and shorter hours and notifying drug store proprietors of the nature of their demand and the possibility of a strike in case of their rejection. Under the proposed wage scale, registered clerks will receive $50 a week; a first class junior clerk will receive $35 a week; a second class junior clerk $25 a week; and a third class junior clerk $15 a week. This will affect about 8,000 drug clerks in New York City, including the registered pharmacists in all hospitals in the city.

Obituary Notes.— Dr. JULIET H. SEVERANCE, one of the first women in this country to graduate as a physician, who practised medicine for many years in DeWitt, Iowa, died at the home of a relative in New York City on September 2, aged 86 years. Dr. Severance was well known because of the interest she took in antislavery, woman's suffrage, temperance, and religious subjects.

Dr. EDWARD R. SISSON, died, after a long illness, at his home in New Bedford, Mass., on Aug. 26, aged 91 years. He was a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1858. In addition to his professional interests he was an enthusiastic yachtsman and huntsman.

Dr. RALPH RAUM BOYLE died at Philadelphia, on Aug. 26, at the age of 53 years. He was graduated from Jefferson Medical College in the class of 1887.

Dr. BENJAMIN B. WILSON died at Philadelphia, on August 28, at the age of 90 years. He was graduated from the medical department of the University of Pennsylvania, in the class of 1850. He served in numerous capacities in different parts of the United States during the Civil War, and he was from 1867 to 1883 professor of surgery in the Woman's Medical College of Pennsylvania and surgeon to the Woman's Hospital of Philadelphia. He was an honorary member of the Association of Military Surgeons of the United States.

Dr. JOSEPH ZEISLER, professor of dermatology in the Medical School of the Northwestern University, Chicago, since 1889, died suddenly at his summer home on Mackinaw Island, Mich., on August 31, aged 65 years. He was a graduate of the University of Vienna in 1882. He was chief dermatologist of the Mercy, the Wesley and the Michael Reese Hospitals.

Dr. JAMES C. COOPER of Baltimore, a graduate of the University of Edinburgh in 1887, and of the University of Glasgow in 1888, died while on a trip to Deal's Island, on Augsut 21, aged 65 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Aug. 15, 1919.

Eyesight Tests of Railway Workers.—One of the principal railways of Great Britain, the North-Eastern Railway Company, or rather those responsible for its management, a short time ago decided that the engine drivers and the firemen should be subjected to an eyesight test. As a result of the decision the men involved went out on strike as a protest against it, with somewhat disastrous consequences to the industries of the North of England. However, the outcome has been fortunate, for the wise conclusion has been come to that a national eyesight test for railway men should be set up. That the drivers and firemen of trains should be possessed of good vision, or of vision adapted to the special requirements of the service, is too obvious to need argument. Therefore, in the first instance it is necessary to discover exactly what these requirements are. The ordinary standard vision does not fulfill the sight exigencies of the engine driver. Acuity of vision is not enough; it is essential that the engine driver should have not only keen vision, but that this should be associated with a good light sense. Consequently, it is in the best interests of all concerned that the British Government should have intervened, and, through Sir Auckland Geddes, president of the Board of Trade, determined that an eyesight test for railway men should be established at once. Moreover, it may be pointed out that some of the tests which have been employed by the various railway companies in Great Britain are by no means reliable. In fact, one at least of these is distinctly dangerous, for confidence is inspired in the vision of those who have passed it which is not justified. Again, the question of the degree of visual acuity required in engine drivers and firemen is one which calls for a settlement based upon a uniform standard. The standards in vogue among the railway companies of Great Britain, so far as sight testing is concerned, are not uniform, and the remark applies especially to testing for color vision. Tobacco amblyopia is another matter of vital importance in the conduct of an examination of the visual capacity of railway engine drivers and firemen. The affection is more prevalent than formerly, and particularly affects color vision. Engine drivers and firemen who smoke should be tested with comparative frequency. The entire question of the eyesight of railway men is of the first importance, and it is well that it should be dealt with promptly and in such a manner that the lives and limbs of travelers will be safeguarded as far as is possible.

The Order of Foresters and Disabled Men.— The Order of Foresters is one of the oldest and most powerful benefit societies of the world. Recently this order has held a conference in Norwich, and among other questions discussed the existing regulations of the order regarding disabled men. These regulations read that he who is minus a foot or hand, an arm or leg, or suffering from a rupture, except as provided by general law 37, section 1, shall not be eligible to the benefits of the society. The executive council of the order, at the recent meeting, expressed their opinion that it was desirable to strike out the above paragraph. It was pointed out that through the accident of war many men had been deprived of legs and arms or otherwise maimed or disabled. It was argued that, as a rule, these men were perfectly healthy, and it was not just that they should be excluded from the benefits of the order. It was further argued that if any one had the misfortune to lose a leg, an arm, or an eye, it generally made them more careful for the remainder of their lives. The argument that carried the greatest weight was that these disabled men had come by

their disabilities in the service of their country and that it would not be fair or patriotic to debar them from the benefits of the society. The recommendation that they should be included in the benefits of the order was carried with few dissentient voices.

Weekly Housing Report.—The Ministry of Health is going ahead with its plans for providing adequate and sanitary accommodations for all classes throughout the country. In Great Britain, although it is mainly an industrial land, the scarcity of housing is as manifest in the country as in the cities and in the industrial centers. True it is that in some thickly populated districts the one-room accommodation for a family is in evidence, and that housing in general does not meet the demands from many standpoints. But in the agricultural parts of the country cottages for laborers have been for long deplorably scarce, and it may be said that good houses are required as urgently in the country as in the cities. By some the British Government is criticised sharply for initiating an immense scheme of housing reform which will necessitate the expenditure of vast sums of money. On the other hand, it is contended that, as the health of the people comes before everything, such an expenditure is highly advisable. The Ministry of Health issues weekly reports on the housing progress, and it is stated in the report given out for the week ended August 2 that the number of new schemes received during that week from local authorities and public utility societies was 211. The total number of schemes which had been submitted up to that date was 3,797, representing an area of about 41,000 acres. At the average rate of 10 houses to the acre, this area is sufficient for the erection of 410,000 houses. Dr. Addison, the minister of health, is pressing forward the housing campaign by every means conceivable, and it appears as if his department, which is under his direct control, may establish a record for activity up to the present time unknown in a British Government office.

War Section of the Royal Society of Medicine.—A new section of the Royal Society of Medicine for dealing with all questions affecting medicine and surgery in the navy, army, and air force, has been established under the name of "War Section." The first meeting of the section will be held on Monday, November 10 next, when a paper will be read by the president of the section, Surgeon Rear Admiral Sir Robert Hill. The officers and council of the war section comprise a majority of the most prominent surgeons of the British navy and army.

National Health Insurance and the Medical Guild.—There is a very considerable number of people in Great Britain who, although insured, do not care to avail themselves of the services of panel practitioners, but prefer to exercise their liberty of choice and be treated by non-panel medical men. Taking all of the circumstances of the case into consideration, the honorary secretary of the Medical Guild was instructed by Dr. John Playfair, the president, and the executive committee of the Guild, to submit for the consideration of the editor of the *Lancet* and the readers of that journal of the date July 26, 1919, the following suggestions embodied in certain resolutions passed at recent meetings of the Guild: (1) That professional attendance and treatment given to any insured person by any registered medical practitioner acting solely on the usual understanding subsisting between a practitioner and his private patient, shall be recognized as a medical benefit for that person, and such person shall receive a just contribution from money provided for medical benefits toward the payment of such attendance and treatment. (2) That obstetrical practice should not be included within the range of national health insurance. (3) That tuberculosis should be excluded from the range of national health insurance. (4) That the national health insurance acts as at present administered should not be extended, with the exception of specialists' advice to the present insured. (5) That a state medical service is of urgent necessity for the genuinely necessitous classes of the community, and for them alone. It is further stated in this letter that those who prefer to choose their medical attendants are numerous, and increasing annually, and as such is the case it is a matter of justice that those persons should be allowed a money contribution toward payment of such attendance and treatment. More especially when the fact is taken into account that the large sum of money for the medical benefit of those persons is being paid to, or distributed among, the panel practitioners who do not work and never will have the opportunity of working for this money. It will thus be seen that national health insurance does not meet with the approval of a goodly proportion of the British medical profession.

A National Scheme for Dental Treatment.—It was recommended recently by the departmental committee on the British dental act that steps should be taken without delay to recognize dentistry as one of the chief means for preventing ill health, that every possible measure should be taken to enlighten the public as to the need for treatment of diseased teeth, and that such treatment should be available for all who require it. In view of this declaration the British Dental Association has formulated a scheme for a complete dental service which is now under the consideration of the responsible authorities. The secretary stated recently that his association was convinced that in order to coordinate the dental service throughout the country and to control the public dental officers effectively there should be a dental section of the Ministry of Health, under a dental director. The scheme proposed by the association included the following: (1) Dental treatment for expectant mothers and for children up to five years of age. (2) Dental inspection and treatment of all children of school age. (3) Dental treatment for all adults, whether entitled to national insurance benefits or not. (4) Dental treatment as an essential in the cure of tuberculosis and venereal disease. As regards expectant mothers, and children under five, it was recommended that in industrial areas center clinics should be established, each under a whole-time dental officer.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, Aug. 15, 1919.

Belgian Doctors Volunteer for Child Work.—Two hundred Belgian physicians, who, during the war, devoted themselves to caring for orphaned and

needy children in occupied territory, met this morning to outline the continuation of their work on an even larger scale, as one of the most important phases in the reconstruction of their country. They heard Mr. Henri Jaspar, Minister of Economic Affairs, and for long the moving spirit in child-welfare work, outline a bill which will place in every corner of the country, no matter how remote, a completely equipped institution for nourishing infants, and educating and training mothers in their proper care and in the proper sanitation of homes. M. Jaspar thanked the physicians for what they had done in the war, and urged the necessity of strengthening the future generation because the country's fate depended on its vitality. Parliament is now discussing a bill for establishing consultation and nourishing stations in every commune. When this is passed, Belgium will be the first country in the world with such nation-wide provision for infants.

Dr. René Sand, who is just back from America, gave a report on what has been accomplished by the Children's Bureau under Mrs. Julia Lathrop, and in New York under Dr. Josephine Baker, where in the last ten years infant mortality has decreased 10 per cent. Dr. Sand urged Belgian physicians to adopt the minimum standard now governing in America. He also urged a greater use of the intellectual and sentimental force of women in Belgium in caring for children. The need for schools for visiting nurses and social workers and for establishing outdoor playgrounds for children was also emphasized. The speaker paid tribute to the names of M. Jules Lejeune, the prime mover in children's work in Belgium, and M. Henri Velge present secretary-general of the Oeuvres de l'Enfance in Belgium.

Pictures Wanted to Educate the Children.—A plea to all readers of illustrated magazines in behalf of the thousands of children of the devastated regions of France is made by the American Committee for Devastated France. One of the most effective methods of training the eye, giving accuracy to the hand, and in general teaching a child current history is through the medium of pictures, says the committee, and the children can be helped enormously if, after being read, illustrated magazines are mailed to the Comité Américain pour les Régions Dévastées, rue du Cloitre, Laon (Aisne), France, for the children of the Canton of Anizy. The organization says that within two hours' motor run from Paris there is a devastated area of hundreds of miles where no books, nor magazines, nor pictures have penetrated for nearly five years. Thousands of children have no schools nor instruction and neglected they run about the ruined villages and over the shell-filled fields playing with "duds" and touching wires still connected with explosives.

There are still a hundred villages to be helped in this line, and great aid to the work would be the use of all illustrated magazines, French, English, and American. The children could be occupied in cutting out the pictures and making picture-books of their own, classifying the war pictures, the American pictures, reproductions of modern art, great men, etc. The Committee points out that dark winter days are coming, when children can no longer remain outdoors until nine o'clock but must be kept in the cheerless cold dugouts or cellars, or inadequately patched rooms of their ruined home. From four o'clock until bed time there is nothing for them to do. Often a family of ten lives in one cellar. The coming winter will be a critical one for these returned refugees. There is no army in the once occupied district to give food and occupation to the inhabitants. These people are isolated in their ruins, with no contact with the outside world, and no method of transportation. Everything must be brought to them, food, equipment, clothing, household goods, and when the bare necessities are supplied, occupation and diversion are still lacking.

Exchange Medical Teaching.—The provision for reciprocal exchanges by which American universities are being made available to French students and French universities to Americans, has now been extended to the medical schools. In response to a request by the Franco-American War Committee that the president of the Académie de Médecine consult his colleagues as to the best means for establishing an interchange in medicosurgical education between the two countries, Professor Tuffier, who was charged with the inquiry, now reports the adoption of a proposition elaborated by Dr. Dehelly. Postgraduate instruction, including all branches of research in this great field, will be established in France for the benefit of students from the United States. All courses of rapid study which they may desire to pursue will be placed at the disposal of the American students desiring to pass through French centers of medical learning, individually or in groups. Specialists will be directed to the services which may interest them and to the instructors they may seek. The entire organization will be brought close home to young professors in quest of new methods and processes in surgery and medicine.

3. Favus in an Adult.—Charles Wolf reports a case of favus in a soldier, 28 years of age, born in the State of Oregon. This patient, as far back as he could remember, had had trouble with his scalp. He had sought treatment in civil life, but had become discouraged over the inability of physicians to cure him and had had no treatment for four years. The condition passed unnoticed when the man enlisted because he allowed the hair of the nonaffected part to grow luxuriantly, thus concealing the diseased area fairly well. Later the condition was discovered and the patient sent to the Walter Reed General Hospital. The diagnosis of favus was made clinically and confirmed microscopically. The patient at first refused *x*-ray treatment. Various strong antiseptics were, therefore, used, but without any effect. The patient then gave his consent to *x*-ray treatment and he was given one epilating dose, measured by the Holzknecht radiometer. In the course

of several months following this treatment the condition cleared up completely and later new hair appeared. This case is of particular interest because of the presence of favus in a native American and because of its rarity in the adult. The statistics of the American Dermatological Society show that favus is a rather rare disease, the proportion being 0.35 per cent. and that patients are, for the most part, foreign born. The case is of further interest because of the failure of the disease to disappear spontaneously or with the use of various antiseptics, and its probable cure from the application of one erythema dose of *x*-ray.

4. Anomalies of Tuberculosis in the Highlands of Colombia: A New Diagnostic Sign in Incipient Cases.—Jorge Vargas S recalls the fact that physicians of the early part of this century observed a curious evolution of tuberculosis in the great Colombian Highlands. A few years ago this locality was almost free of the Koch bacillus, while today it is infested with this malady, but with pathological peculiarities different from what prevails in the temperate zone, due to the fact that the race does not possess immunity to tuberculosis to any degree. In the clinic of Dr. Josue Gomez, in the Hospital de Caridad of Bogota, from 1896 to 1899, the writer was shown a few cases of pulmonary tuberculosis as a rarity, while cases diagnosed as tuberculosis peritonitis were quite frequent. This, he believed, was tuberculosis of the mesenteric lymphatics in men who did not have ancestral immunity. During the last four years he had observed hundreds of such cases. The three things that called his attention especially to the curious nature of the disease in the highlands of Bogota were the rapid cavity formation, the military forms, and the tuberculous meningitis, the latter being the not uncommon form of acute tuberculosis generally occurring in the sick—more often in women—while convalescing from great hyperpyrexia, principally from typhoid fever. There are, however, numerous cases of chronic pulmonary tuberculosis, there being a difference in that contracted in the highlands and that contracted in sea level regions. The new sign which the writer describes, and has found in 169 cases of incipient tuberculosis, consists of the reinforcement of the whispered voice in the vertex of the affected lung. The sign appears before the disease reveals itself by any other symptom, either auscultatory or percussional, before respiratory inversion and impairment of the supraspinal triangle of the affected side. A stethoscope and a little practice are enough to find it. The mechanism of the sign is very simple. Laennec showed that the first period of tuberculosis is characterized by a peribronchitis. The interstitial peribronchial inflammation increases the density of the lung, and owing to the easy transmission of sound by dense tissues, the larynx and tracheobronchial noises are transmitted in a better way to the ear that auscults, through a tissue of greater density. This explains the respiratory inversion, that is, the reinforcement of the expiration. When the peribronchial injury is not sufficiently extensive to conduct with clearness the tracheobronchial noise, it is sufficient to make the patient repeat in a low voice in each expiration a word rich in consonants. In an instant the ear will perceive the great difference that exists, in the case of incipient tuberculosis, between the healthy and the affected side. From the affected side each syllable is distinctly heard with such force that it reaches sometimes the degree of whispered pectorliloquy. This sign should not be confused with whispered pectoriloquy, which may accompany tuberculous pneumonia of the apex of the lung, which has an acute progress, with blowing and other signs. The Niess sign, consisting of a whispered pectoriloquy in the space situated between the inside edge of the scapula and the columnar vertebrae, is found also in bronchial adenopathy. Its cause is the transmission of the tracheobronchial breath through the hypertrophic lymphatic masses. It has nothing to do, therefore, with the sign described. As counter control of the sign of the reinforcement of the whispered voice, the writer had 140 convalescing and debilitated patients (with uncinariasis, anemia, chlorosis, etc.) under observation, who did not present the sign. This sign appears even before the roentgen rays give a distinct shadow and when there is not yet any other sign either auscultatory or percussional.

2. The Etiology of Influenza.—G. E. Beaumont reviews the work of a number of bacteriologists in respect to the influenza bacillus, and believes he is justied in saying that there is considerable doubt as to whether Pfeiffer's bacillus is the cause of influenza. The examinations of the various bacteriologists comprise those of posterior nasal swabs, sputum, pleural effusions, blood, and post-mortem material. The writer tabulates the results of these various investigations, the net result of which shows that Pfeiffer's bacillus has been found in 51.8 per cent. of cases of nasopharyngeal swabs taken from influenzal patients, cocci being also found in every case. The Pfeiffer bacillus was found in the sputum in 42 per cent. of the cases; in pleural fluids in 8 per cent.; in the blood in 7.8 per cent., and in the lungs and lymph glands in 38.3 per cent. of the cases. He finds that the case for the Pfeiffer bacillus is still further weakened by the fact that it has been found in cases that are not influenzal in nature. Thus, for instance, Fildes examined 71 nasopharyngeal swabs from healthy individuals and found Pfeiffer's bacillus in 21 per cent. This organism does not, therefore, fulfil even the first postulate of Koch for specificity—which states that it shall be found in every case in lesions typical of the disease, and there alone. The writer then considers the alternatives that are left as the cause of influenza—a filterable virus and the cocci. As a result of investigations in this direction it has been demonstrated that in this epidemic a diplococcus, often growing in chains, has been present very constantly in the sputum, occasionally in the blood, nasopharyngeal swabs, and post-mortem material. He then describes his own laboratory work done in collaboration with Captain H. J. B. Fry. The sputum was examined shortly after expectoration. Films were made and stained by the Gram method. In certain cases the sputum was examined daily throughout the disease; in others only one examination was made. The examination of these films shows the presence of a variety of

organisms, and it is suggested that certain of these are stages in the life history of a mycotic parasite—that, in other words, influenza is a mycosis. The evidence to support this view is detailed. The films have yielded the following forms: hyphæ, large spores, coccal clusters, small spores, tetrads, mulberry masses, chains of cocci, and bacilli. In all cases in which films were made from cases of influenza a large number of the above stages were seen, the commonest being coccal clusters, hyphæ, large spores, and diplostreptococci. Pfeiffer-like bacilli were not noticed. A pure culture of large spores was obtained which grew out into hyphæ, large spores, small spores, and coccal forms. Single colonies ever on subculture were not pure, in that they did not contain only one organism. Specimens were collected from six cases of influenza that had attacks of enteritis during their illness. They were passing liquid motions containing bright red blood. These specimens in all cases showed large spores, gram positive and gram negative. In addition there were coccal clusters of gram negative and gram positive elements, hyphal filaments, diplostreptococci, mulberry masses, and bacilli. The examination of the urine in seven cases gave similar results in 86 per cent. of the cases. Blood cultures were made in 13 cases and gave 7.7 per cent. positive results. The writer concludes that it is possible that influenza is a mycosis, not necessarily in all cases a bronchomycosis, but perhaps in some an enteromycosis, and that their observations appear to demonstrate that such an organism is always present during the disease.

5. Notes on the Influenza Epidemic in the Egyptian Expeditionary Force. J. D. Benjafield.
6. An Address on Goitre. H. J. Boyd.

1. The Bacteriology of Chronic Nasal Catarrh and Its Treatment by Autogenous Vaccines.—Leonard Mackey records his observations made on patients suffering from (1) recurrent acute nasal catarrh, (2) chronic nasal catarrh, or (3) chronic post-nasal catarrh, not including simple brief nasal catarrhs, nasal infections associated with polypi, diseases of the antrum or sinuses, atrophic rhinitis, or any discoverable surgical lesion. He emphasizes the importance of making the cultures and incubating them as soon as the swabs have been taken. He says it is impossible to place any reliance on a nasal swab sent through the post, for two of the most important germs found in nasal catarrhs, namely, *B. influenzæ* and pneumococcus, die quickly if the swab gets cold, while germs of minor importance, such as the staphylococci and diphtheroid bacilli, actually multiply in the mucous on the swab. He states that the nose is not, like the mouth and throat, a breeding place for all sorts of germs. Cultures made in the way the writer describes from healthy persons he finds here no resemblance to cultures made from patients with nasal catarrh. In catarrh almost invariably a profuse growth is obtained of the causative germ, which is usually the pneumococcus, *B. influenzæ*, *Micrococcus catarrhalis*, Friedlander's bacillus, or a special type of streptococcus. Other organisms found are diphtheroid bacillus, *Staphylococcus albus*, *M. tetragenus* and *B. proteus*. The pneumococcus, however, is easily first as the causative agent and the influenza bacillus second. Of 558 cases of chronic catarrh studied by the writer during the past seven years, 351 cases showed pure cultures and 207 mixed cultures. While he does not believe that neurasthenia and gastritis are often due to nasal infections, he believes that chronic nasal infections are capable of producing those and many other diseases, and that a routine investigation of the nasal passages would be worth making in many instances of chronic and inexplicable disorder. He asserts emphatically that chronic and recurrent bronchitis is frequently due to post-nasal catarrh, and that the causal and dominant germs in the sputum can usually be obtained in pure culture from the nasal swab. The point is stressed that obstinate nasal affections in young children frequently depend upon adenoids, even though such adenoids do not cause nasal obstruction. Nasal infections are commoner than pyorrhea and much more important. They are a cause of pneumonia and bronchitis and lead to pulmonary complications after anesthetics. Otistis media and its complications begin as infections of the nasopharynx. That chronic post-nasal infection may prepare the way for tuberculous infection cannot be doubted. During the past seven years the writer has treated 500 cases of chronic catarrh with autogenous vaccines. Most of these patients were sent by their physicians because ordinary measures had failed to cure them. In the case of children vaccines were seldom used because chronic catarrh in children is generally due to adenoids and can be cured by the surgeon. The vaccines used were made from the germ or germs which were believed to be responsible and always from the primary cultures when these were pure. Mixed vaccines were made when two or more catarrhal germs grew profusely on the plates, or when, as sometimes happened, a different infection was found in the two nasal passages. The maximum dose of pneumococcus and streptococcus used was always 150 million for an adult, and of the other germs 300 or 400 million. The results were good. In many cases the patient was pleased and grateful and believed himself cured, there being no sign of catarrh, but the same germ is still in his nose, and after two or three years the catarrh will reappear. In one-half the cases the catarrh is cured and the nasal passages are normally sterile. In about one-third of the cases the catarrh persists in a modified degree. In the case of patients with secondary disorders, the results of the treatment are still better, for whether the catarrh is cured or only reduced, the general health is improved and the patient gains weight and strength.

3. Alternation of Generations and Its Bearing Upon Cancer.—J. Beard discusses an article by Dr. W. M. Crofton dealing with the former's theory of the alternation of generations and the Abderhalden pregnancy reactions. Beard contends that Crofton's article is one from which it would be impossible for any opponent of his embryological conclusions as to cancer and the rôle of pancreatic ferments in its treatment to cite anything adverse to any statements of his ever printed with reference to cancer and its treatment. In his opinion, Abderhalden's work and conclusions might be quoted as supporting from the purely stereochemical side his embryological work, and later his stereochemical conclusions upon the problems of cancer. Crofton holds that Beard has been led astray to advocate in the treatment of cancer the pancreatic ferments, instead of the internal secretion of the pancreas gland. Beard's opinion of the "internal secretion" of the pancreas gland is that at present it stands in exactly the same position as the gland itself did prior to Corvisart's researches in 1857, when physiologists and physicians alike held that it had no digestive functions whatever. It has never been demonstrated by anyone that the "internal secretion" of the pancreas gland will perform any physiological work at all. Beard still insists that trypsin and amylopsin scientifically administered are curative in cancer. In disproof of this the many failures may not be referred to, for as the late Professor D. J. Cunningham once remarked, "Negative results never prove anything at all in science." The explanation of the many failures is easy. Some, even many, cases failed because the treatment was undertaken too late, for it has never been Beard's view that trypsin and amylopsin, powerful though they might be, could be considered a useful alternative to Extreme Unction. Other cases failed because the preparations used

were, to say the least, not suitable for the treatment. The author is now convinced that another cause of failure is to be found in the mode of giving the injections, hypodermically or intramuscularly. It has always been his own opinion that the proper manner of giving the injections is intravenously as recently advocated, with success claimed in the first case tried by Dr. W. W. McDuffie of New York. As to the use of "internal secretion" versus trypsin and amylopsin, this matter could be easily set at rest. But the onus of making the test is upon Dr. Crofton, not upon Beard, who is quite skeptical regarding any influence of "internal secretion" upon cancer cells. Beard summarizes his present scientific position thus: In all the years that have elapsed since his Liverpool lecture of January 20, 1905, the author says, nothing whatever has occurred to alter in the least his convictions regarding the nature and treatment of cancer.

Investigations into the Etiology of Influenza.—Burckhardt concludes his article as follows: The flora of influenza having been described, what is the true cause? Is it Pfeiffer's bacillus, a streptococcus or a symbiosis of the two with others added, or is the cause still unknown? If the latter, is the cause a bacterium or something wholly unimaginable? Pfeiffer's germ must be left out of count, yet this organism is quite able in itself to cause local epidemics of influenza, as shown by Kruse in 1895. There is such a disease as a Pfeiffer grippe. The author's patients were all made to cough on glass platelets, and upon only 20 per cent. of the latter were Pfeiffer's bacilli present. How then can this bacillus or people who are carriers of it disseminate the disease? The socalled grippe streptococcus seems even harder to incriminate by the coughing test, so that we must regard it only as a cause of complications. This is true also of the pneumococcus. A symbiosis of infecting germs is not demonstrable in the coughing test. The author's idea of symbiosis is one germ which prepares the soil and another which attacks the depreciated organism, rather than a double virus. There are numerous examples of the first type, while of the second we have Vincent's angina. In 1847 a leading authority made an increase of atmospheric ozone a factor, and even to-day a tertium quid connected with weather conditions has been adduced. The author's studies have convinced him that mild and severe cases may have quite different causes. If the light, harmless form was an attenuation of the severe form, the behavior of the disease would be different from what has thus far been seen. Mild and lethal cases may be seen side by side. The lethal case is evidently due to the streptococcus plus some unknown contagium vivum. In the mild case the extreme diffusibility and rapid passage speak for the contagium vivum in a pure state. We see this association in several of the great contagious maladies. Kruse in 1914 filtered the secretion of an ordinary cold and succeeded in infecting other men. Similar experiments were repeated abundantly in the recent pandemic. Might not the virus in the two cases be the same? It would be difficult to exclude the virus of common cold in these experiments. The author, like numerous other bacteriologists, has discovered a microorganism which while minute enough to go through a filter is nevertheless visible in cultures. This, he thinks, is the real motivation of the pandemic, while the lethality is due to a special grippe streptococcus.

A Study of 168 Cases of Prostitution.—Dr. Del Valle Atiles took his material from the Woman's Hospital of San Juan. In great contrast with the finds of most other cities two-thirds or more of the girls had no occupation and apparently had never worked. There were comparatively few domestics and factory girls. The fathers of the girls were very largely in poor circumstances and followed the cheapest forms of industry. Poverty then is the chief cause, with the natural result of the male and female members of the family being huddled together at night, the lack of clothing sufficient for modesty, etc. These factors lead to precocious sexual development. Among such poverty-stricken people prostitution seems the only way left the girls to sustain life. Early prostitution is, of course, common, and the author saw girls of from 10 to 14 leading this life. Whether the parents connive at this fate and accept money from their daughters does not appear, but in many cases the parents were epileptic, alcoholic, tramps, etc., and of very low sexual morals. Illegitimacy is not mentioned. The girls gave, as usual, many reasons for the choice of an immoral life, but very few admitted that their parents sent them on the streets. The greatest number for any one reason was 38, which group accused proxenitism (which might be rendered organized white slavery). In a group of 24 no motive could be elicited. Twenty-two gave orphanism, and in one group of 23 inability or disinclination to work was the motive. Eighteen had been seduced and abandoned. Many minor motives were given, as when four girl thieves became prostitutes to make robbery easier. The number of alcoholics was 24 (San Juan is "dry"). Thirty-three women had had one or more children. All but two of the 168 were born in Puerto Rico. The number who had been married was 34.

Anasarcous Form of Cancer of the Stomach.—Gouget states that it is not so uncommon to see cancer of the stomach evolve in the midst of the picture of nephritis with anasarca, but very rare to see an anasarca develop as the expression of simple cancer of the stomach. In 1877 Chesnel devoted a thesis to latent cancer of the stomach in 12 cases, of which there was present a cachectic edema. In 1898 Bouveret, in his book on cancer of the stomach, mentions this Chesnel type in which a blood alteration of a constant type is responsible for anasarca, at least, of the lower extremities, as well as dropsy into the serous cavities. He had himself seen cases of this type. One, of course, thinks first of nephritis, but every evidence of this malady is absent. For some reason the symptoms of cancer seem to be in the background, although a routine examination of the stomach contents will reveal the chemism of that condition. Soupault, in 1896, in his book on diseases of the stomach, emphasizes the following: a great preponderance of the anemia with an anasarca, which, while most commonly seen in the lower limbs, may be total. The degree is not high, the condition being rather a puffiness. Hayem, disregarding edema as only secondary to anemia, classes these cancers as anemic. Hence, when confronted with such a case one thinks of three conditions—nephritis, heart disease, and cancer of the stomach. The author makes the total material in which total anasarca was present 13 cases. Of this number Chesnel has reported 5, and other authors 7. The author adds his personal case. Three types are comprised. The first exhibits anasarca and weakness, without gastric symptoms. These patients live about three months after admission to hospital and the diagnosis is made only at autopsy. In the second type the evolution of the disease is very rapid, all being over in a few months from the start. Gastric symptoms may or may not be present and in the former case the anasarca is only a complication of the ordinary type of cancer. While superficial edema is present there are also collections of fluid in the serous sacs. After the development of edema the gastric symptoms become less pronounced: thus vomiting may cease. In one case, at least, the anasarca developed in serial attacks with intermissions, the last attack being of very high degree. In some cases one feels that the edema is simply a terminal phenomenon. In the third type the duration of the disease is very long. The patients apparently recover temporarily and then after a longer or shorter interval the symptoms return. The duration of this free interval may be a year or more. The gastric symptoms seem equivocal.

Second Day—Tuesday, June 17.

Functional Impermeability of the Cardia.—Dr. S. J. MELTZER of New York presented this communication. Under "functional impermeability" Dr. Meltzer said he meant to discuss cardiospasm. According to Osler this was a rare occurrence. Dr. H. S. Plummer had had 400 cases. About thirty-one years ago the writer said he had published a paper on dysphagia. He had had the courage to establish a new disease, but not the courage to give his name to it. Now it was known as cardiospasm. In 1880, while working on the physiology of deglutition, he said that one of the things he believed he had discovered was that in each act of deglutition a wave of inhibition ran ahead of the contraction of the esophagus. In deglutition the esophagus became relaxed and then contracted again; that was also true of the cardia. All contractions were combined with inhibition. At the time a flexor became contracted, an extensor became inhibited. In 1895 the law of reciprocal innervation was published. Stimulation of certain parts of the intestine was found to produce a contraction of the parts below and an inhibition of the parts above. He had seen for the first time a woman, who for nineteen years could not bring down food from the esophagus into the stomach; and in studying her case he came to the conclusion that it was a new type—a chronic contraction of the cardia. The cardia was always in a state of contraction, and the possibility for deglutition to bring down the food from above into the stomach depended on several things. The tonus of the cardia must be inhibited, and assuming that the cardia was inhibited, the degree of the contractility of the lower part of the esophagus must be increased at the same time, or the food would not pass down. Dr. Meltzer said that after his first publication a number of cases were described. Mikulicz reported cases and stated that he had, by means of his esophagoscope, seen seven cases of chronic spasm of the cardia, and Mikulicz gave it the name of cardiospasm. He omitted to mention Dr. Meltzer's name, but later he published an article in which he called it the syndrome of Mikulicz and Meltzer. He made a mistake in that he thought the cardia was always open; he found that was not the case on observation with the esophagoscope. The speaker said that whether there were cases where the cardia was open was not known. He discovered a simple way to recognize cardiospasm and that was by the constant absence of what he termed the "second deglutition sound." The constant absence of this sound was an indication of cardiospasm or what he preferred to call functional impermeability of the cardia, which included a diminished contractility of the lower part of the esophagus. He refrained from a description of the deglutition sounds and the method of ascertaining them. These sounds were studied in a very complicated way. In cardiospasm this sound was absent.

Dr. H. S. PLUMMER of Rochester, Minn., said that in the early '90s he was interested in cardiospasm. In 1878 Zenker published a description of this condition, based on postmortem specimens. There was nothing in regard to the mechanism or the etiology of the condition. It struck him as wonderful that Dr. Meltzer was able to put together this description which held good for many cases. They had not been able to gain much information as to the etiology of the inhibition of the cardia. In the majority of cases the history and the findings seemed to point out that the constriction at the cardia was predominant, and there was an obstruction before the passage of food; the lack of tone in the esophageal wall came in, or at least was the dominant reason why the esophagus dilated. There was one phase of it which he had pointed out in his early paper, and that was the presence of pain, and this pain feature was worth while mentioning. It might come some months before there was any history of dysphagia. He had seen cases that had been operated on for gallstones. He could see nothing in the description of the pain that was different from biliary colic. None of these patients had gallstones; they were all relieved by dilatation of the cardia. In one case a patient had repeated attacks for four years, requiring morphine. She was esophagoscoped, and when the instrument touched the cardia, she had a sharp attack of pain. Dr. Plummer said he wondered whether these patients might not have gallstones at the same time; but he had, however, never seen a case of gallstones accompanying cardiospasm, or a case of gallstones in which cardiospasm was present.

Dr. JOSEPH SAILER of Philadelphia said he would like to speak of one point. Dr. Meltzer spoke of the inhibition in the gastrointestinal tract, namely, that the nervous contractions had a tendency to relax the sphincters, and where the sphincters were contracted, other parts of the intestine were relaxed. He thought by stimulating the autonomic nervous system, where there was functional contraction of the sphincters, relief could be had. He had used pilocarpine. It was extremely rare to get accurate observations on the actions of drugs, as patients often got well spontaneously. Nevertheless, in all the cases in which he had used pilocarpine there had been no evidence that pilocarpine increased the spasm, but, on the other hand, the patients had done well when it was a functional condition.

Dr. MELTZER, in closing, said he was speaking of chronic cardiospasm. Those patients did not recover. The patient he described had had it for nineteen years, when he first saw her, and twenty-five years in all. Dr. Plummer had had an extensive experience, and the speaker hoped he would make a distinction between the acute cases and those chronic cases which persisted.

A Case of Perforated Gastric Ulcer with Abscess Formation; Perforation Through the Lung with Spontaneous Recovery.—Dr. JULIUS FRIEDENWALD of Baltimore read this paper. The patient was a man, fifty-one years of age, who had had symptoms of gastric ulcer for a long time, when he was suddenly seized with an acute, excruciating pain in the upper abdomen, which necessitated two hypodermic injections of morphine to procure relief. His acute illness persisted for a period of ten days, during which he had considerable pain in the left lumbar region, with fever, cough, and purulent expectoration. Following this there was a gradual relief with cessation of symptoms and the patient made a spontaneous recovery.

How Partial Paralysis and Regional Paralysis of Intercostal Muscles Affect Lung Ventilation.—Dr. CHARLES F. HOOVER of Cleveland, Ohio, made this presentation. He presented observations on patients with paralysis of some or all of the intercostal muscles as affecting respiration. An adult with paralysis of all his intercostals would not experience any discomfort when lying at rest. He had never seen an instance of paralysis of all the intercostals in a child. He thought a child in that condition might have much discomfort. But an adult could tolerate complete paralysis of all the intercostals when lying at rest. He had seen an instance of unilateral paralysis in a little girl, who had had a fall and had paralysis of the left arm, left leg and all the intercostals on the left side, and the left side of the diaphragm. She had had a hemorrhage into the spinal cord proved by lumbar puncture. This child had no discomfort, was not cyanotic, and the question arose as to why a child with left-sided paralysis and no ventilation of the left lung could lie still in comfort, whereas a child with obstruction of the left lung, due to a foreign body or to obliteration of the left lung in pneumonia immediately would become dyspneic. This child was not dyspneic. How did she compensate for it? There was no evidence that the blood driven from the left lung into the aorta was not venous blood. The only explanation was that the mediastinum must have moved toward the left side so that there was some ventilation of the left lung, and that in inspiration it would move to the right and in expiration to the left. When one had a picture of the upper intercostals on both sides paralyzed, it was a different situation. The speaker said he had a case of a boy two

and a half years old, on whom the surgeons were going to operate for suspected stenosis of the trachea. The child breathed with comfort when at rest, but when crying or moving he would start a vicious circle and would show signs of suffocation. On palpating the chest, it was observed that the manubrium was not retracted in inspiration, but from the second to the seventh ribs all were violently retracted during inspiration. The eighth rib was the first that moved outward, so that during inspiration there was a violent movement of the abdomen and the upper portion of the chest was retracted, so that there was a violent seesaw between the upper and lower chest. It was a difficult situation to analyze. What happened was that during inspiration the upper portions of both lungs were compressed, consequently the lower lungs were distended with alveolar air from the upper lungs, and in expiration the reverse took place. There were absolutely no neurological signs in this child, no loss of sensation in the trunk, no loss of power over the abdominal muscles; certainly the diaphragm was very active and there was no disturbance of innervation of the lower extremities. An *x*-ray showed caries of the upper sixth dorsal vertebræ. It was hard to explain why this paralysis was the only sign of tuberculosis. Dr. Hoover said his curiosity was aroused to see whether he could find other instances of paralysis of isolated groups of the intercostals. He found a case of a man with syringomyelia. This man had a paralysis from the fourth to the eighth intercostals and paralysis of the muscles of the left half of the abdomen. By fluoroscopic examination one could see no flattening of the diaphragm. In this case every time the man coughed the abdomen would rotate to the right.

Dr. S. J. Meltzer of New York said he would like to call attention to a paper he had published years ago on "Factors of Safety," and he had shown experimentally since then that one might not only remove the entire left lung or the entire right lung, but the entire left and one lobe of the right, and it would cause no change in respiration. One could not compare this reduction of the lung with mechanical interference with respiration or with the elimination of the lung in inflammatory processes as pneumonia. In pneumonia there was something else besides the elimination of the lung—there was the condition of the lung and the condition of the respiratory center.

Dr. Lewis A. Conner of New York said in connection with Dr. Hoover's question as to whether in young children complete paralysis of all the intercostal muscles could be borne without cyanosis and distress, there were few cases on record. He had had an opportunity during the poliomyelitis epidemic in New York of seeing some cases, and he recalled distinctly that in those in which the child was quiet in bed there was no distress, but the least effort would bring on cyanosis. Dr. Conner said he was interested in Dr. Hoover's explanation or suggestion for an explanation as to just why an individual who had complete paralysis of the left intercostal muscles, including the left side of the diaphragm, should not have had more distress and cyanosis, and he suggested that it was because during inspiration there was a movement of the mediastinum to the other side, which permitted a certain amount of respiration and expansion of the left lung. Dr. Conner did not see how that would satisfactorily explain it, because it would seem that the respiration in the right lung would be diminished by the amount of movement that was added to the left lung.

Dr. Hoover, in closing, said in regard to Dr. Meltzer's remark about the tolerance of the loss of the lung, he did not wish to discuss the tolerance; the point he had tried to bring out was that the patient dd not show any discomfort or cyanosis. In lobar pneumonia one saw a man with cyanosis and one asked him if he were short of breath, and he would reply "no." The patient was breathing rapidly, because the unaerated blood from the lung was poured in the left ventricle, but the man did compensate for the increase CO_2. He could compensate for that, but there was a dissociation between anoxemia and air hunger. In regard to Dr. Conner's suggestion, he thought the doctor had rather lost the point of his contention that it was a reciprocal rebreathing. It was necessary that one part of the lung be diminished in volume during the inspiratory effort.

Chest Wounds in War, from the Medical Standpoint.—Dr. G. Shattuck of Boston, Mass., presented this topic. He said that while the diagnosis and the management of chest wounds was essentially medical, it was necessary to have close cooperation between the medical and the surgical sides. The diagnosis was rendered difficult by the fact that many conditions might be present at the same time. The simple hemothorax did not present many difficulties. There was, however, a hemorrhagic infiltration of parts of the lung, due to the damage by the missile. Besides the blood in the pleural cavity and the hemorrhage infiltration, pneumothorax might often have to be considered. Pneumothorax was not as common as one would expect in wounds of the chest. The recognition of a small pneumothorax would be difficult for a variety of reasons. In the first place, it might be absorbed within a few days after the wound; and when a patient first arrived from the field station his condition would be such that a prolonged examination would be unwise. Therefore, examinations made in the early stage should be generally limited to absolute essentials. Then the *x*-ray examinations frequently had to be made, and made in the recumbent position, in order to avoid danger from sitting the patient up. A small pneumothorax would probably be overlooked by the *x*-ray man, who looked at them in the recumbent position. Moreover, the breath sounds over a pneumothorax had a distinctly amphoric quality. This was striking. He had again and again observed amphoric breathing and had aspirated and got fluid only. Besides the presence of air and amphoric breathing and changes in the lung, due to the missile, another change must be considered. There might be massive collapse in the lung opposite to the one wounded. One of the remarkable things was the displacement of the heart. A moderate hemothorax would generally displace the heart more or less, and a large hemothorax would cause a displacement of the heart toward the inner side. Massive collapse drew the heart to the same side. It was hard to explain the findings on examination. The signs were often mistaken for pneumonia. The important thing was the position of the apex impulse. The *x*-ray findings were also to be noted. Collapse might occur, not only in the uninjured lung, but also in the lung which had been injured. He did not mean that consequent upon the presence of fluid in the chest, but he meant the collapse occurring in the uninjured lung might also occur in the injured lung. It might be present on both sides of the chest. There might be extensive pulmonary edema, which rendered it difficult to determine the other signs. Emphysema might be present and give a tympanitic note rendering percussion entirely valueless.

Dr. H. Sewall of Denver said he would like to know the doctor's explanation for the collapse of the uninjured lung. In pneumothorax he thought the heart was pushed over, and in the doctor's explanation he said the lung was drawn over.

Dr. C. F. Hoover of Cleveland, Ohio, said that the thing that had interested him a great deal was the bronchial breathing, or the elevation of the pitch of the breath sounds over fluid. His students seemed to be astonished to learn that that was so. The navy preferred submarine signaling to signaling through the air. Now, water in the chest cavity was a better conductor of sound than air. And the reason this was not detected was on account of the reprehensible practice of men using the stethoscope. If they would apply their ear to the chest with the mastoid against the chest wall, they would pick up loud bronchial breathing, whereas if the sound passed through the air of the stethoscope, it was lost. He taught his students to call a stethoscope an obturator. An elevation of the pitch of the respiratory sound was the first evidence of fluid accumulating in the chest cavity. When the intensity was diminished it was due to thickening of the visceral pleura when the patient had had a deposit of lymph that acted as a screen preventing the transmission of the sound.

Dr. J. Sailer of Philadelphia said that Dr. Shattuck's experience was with the acute cases. His own

experience was with the chronic cases. In those cases the therapy was entirely surgical. The function of the medical man was to aid in the detection of abscess and in the decision as to the type of aspiration. In many instances patients improved by continuous suction aspiration so that there was an opportunity for the lung on the affected side to expand, and this had the double effect of relieving the patient of his dyspnea and, at the same time, for some reason it cleared up the empyema more rapidly than it did in the other cases. Just why this occurred without free drainage of the empyema, he could not explain. Another question brought up was that of the removal of foreign bodies that remained in the thorax. Dr. Sailer said he did not know that the medical men had sufficient experience to add very much except in the supporting way to go in and remove the foreign body. But from the standpoint of physical signs, he did not think of any class of case he had ever seen that had added more to his knowledge of the signs of the chest than the study of these gunshot wounds. The most remarkable feature was the tracing of the course of the bullet through the chest. It seemed that in some cases of perforating wounds of the chest it was impossible for the patient to survive.

Dr. SHATTUCK, in closing, said in reply to Dr. Sewall's question in regard to the cause of collapse, that he was not prepared to say anything about it. He thought the condition was obscure. The remarks of Dr. Hoover about bronchial breathing, he thought, were aside from the point. He was not surprised to hear bronchial breathing over fluid. The point that was exceptional was that the breath sounds were less bronchial than they were amphoric. It was the modification of the breath sounds in these cases that struck him as of special interest.

Factors Influencing Recovery and Resolution in Pneumonia, with Special Reference to the Chemistry of the Exudate.—Dr. FREDERICK T. LORD of Boston made this presentation. He said that humoral immunity in pneumonia might be combined with local biochemical changes favoring recovery and resolution, as suggested by the following data: (1) *Acidosis in pneumonia:* Various observations had shown that in the metabolism in pneumonia a considerable amount of acid was produced. This was indicated by a diminished CO_2 content of the blood, an increased titrable acidity of the urine, increased ammonia output, increased alkali tolerance, and the demonstration (by Palmer) of a large amount of an organic acid in the urine. (2) *Partial isolation of pneumonic lung:* Partial isolation of the pneumonic lung (demonstrated by Kline and Winternitz) might favor such a local biochemical change as an increase in the H. ion concentration of the exudate without a change in the H. ion concentration of the blood. (3) *Acid death point of pneumococci:* As shown by Lord and Nye, glucose bouillon cultures of the pneumococcus, allowed to grow and die out, reached a final H. ion concentration of about 5.1, and the acidity was the most important bactericidal factor. The exposure of living pneumococci to 5.1 or higher H. ion concentration showed that the organisms did not survive longer than a few hours at about 5.1. They lived in suitable media for at least many days at 7.4 to 6.8. In the intervening H. ion concentrations, 6.8 to 5.1, the pneumococcus was killed with a rapidity which bore a direct relation to the H. ion concentration, *i.e.*, the greater the acity, the more rapid the death. (4) *Dissolution of Pneumococci:* Dissolution of pneumococci took place in lower H. ion concentrations than about 5.0 and was most marked at 6.0 to 5.0. Some dissolution also took place toward the more alkaline end of the scale. (5) *Acidity of the pneumanic lung:* The H ion concentration of the pneumonic lung reached about 6.0 in fatal cases. In one dog with experimental pneumococcus pneumonia, killed on the third day, the H. ion concentration of one involved lobe was 6.0 and that of another 5.4. From the former pneumococci were grown in pure culture, but from the latter, no pneumococci were obtained. (6) *Relation of proteolytic enzymes in pneumonic lung to H. ion concentration:* The pneumonic lung contained a proteolytic enzyme capable of digesting coagulated blood serum at H. ion concentrations of 7.3 to 6.7 and inactive in more acid concentrations. It also contained a proteolytic peptone splitting enzyme operative at H. ion concentrations from 8.0 to 4.8, but most active at 6.3 or 5.2. The findings suggested an explanation of recovery from pneumonia in the course of which humoral immunity was assisted by local biochemical changes. Acidosis in pneumonia might be due to partial isolation of the pneumonic lung, permitting a local increase in H. ion concentration, the excess of acid formed in the exudate gaining entrance to the circulation. Dissolution of the pneumococcus might proceed at first slowly and later more rapidly as the local acidity increased. When the H. ion concentration reached the acid death point of the pneumococcus crisis and recovery followed. The findings also suggested an explanation of resolution in the course of which the fibrinous exudate was locally split to a form in which it might readily and harmlessly be absorbed. With the breaking down of the cellular exudate, and enzyme digesting protein (fibrin) in weakly alkaline and weakly acid media was liberated. As the acidity increased, the action of this enzyme ceased. An enzyme capable of splitting peptone to aminoacid nitrogen, also active during the proteolysis of the fibrin, was still further activated at a H. ion concentration of 6.3 or 5.2. The exudate might then be dissolved and resolution take place.

Dr. EMANUEL LIBMAN of New York said that the question of acid production by pneumococci was of the greatest interest. In 1901 in a paper dealing with the peculiarities of bacterial activity on media containing carbohydrate, he pointed out the great importance of acid production in the body by bacteria. At that time, he found that while pneumococci produced considerable degrees of acidity on such media, precipitation of the protein did not occur unless there was over 1 per cent. of the carbohydrate present. Streptococci, on the other hand, possessed this faculty even in the presence of 1/10 of 1 per cent. of glucose. In the body, conditions must be quite different. It had been shown by Rosenow, and later by Longcope, that if one grew pneumococci in normal human serum, very little acid was produced, but if grown on serum of patients suffering from pneumonia, very marked acid production and coagulation developed. It was believed that the penumococci had developed the power of producing acid from glycoproteins. In a patient suffering from pneumonia, there would, on theoretical grounds, be present very marked acid production with precipitation of protein.

Dr. S. S. COHEN said that in connection with Dr. Heist he had been making observations on the toxic qualities of the exudate. He considered this an important field. He called attention to the fact that one could get out of the pneumonic exudate a toxic substance which one could not get out of the normal lung, and which caused death in mice in a very few minutes and hemolyzed human blood in the test tube.

Dr. LORD in closing said, in regard to Dr. Hoover's question, the H. ion concentration of the pneumonic lungs was determined by the colorimetric method after dialysis of the press juice obtained from the lungs. In one case the colorimetric determination was checked by the electrometric methods. In answer to Dr. Cohen, he would say that he could only speculate as to the source of the acid, which led to an increase in the H. ion concentration of the pneumonic lung. Perhaps the most likely source was the splitting of the small amount of sugar in the blood to lactic acid. There were, however, other possible sources.

A New Method for Testing Immunity by Means of the Whole Blood, with Especial Reference to Pneumonia and Its Prophylaxis by Bacterination.—Drs. S. S. COHEN and G. D. HEIST of Philadelphia made this presentation, read by Dr. COHEN. He said that his work on the subject developed as a collateral issue out of certain clinical and experimental studies upon pneumonia, in which, for some years past, he had had the cooperation of Drs. Kolmer, Heist, and others, and which had been in part reported. One phase of the work concerned immunity. They wished to know whether certain drugs modified favorably or unfavorably the development of the disease; also, whether the existence of natural or artificial immunity in men or animals could be demonstrated by a better or simpler

method than agglutination, and whether the existence of protective substances in the blood, or recovery without their development could be demonstrated, after certain prophylactic or therapeutic measures. The results with serum, defibrinated blood and citrated blood were inconstant and contradictory. Remembering an observation of Wright's which, however, he had not published, namely, that the whole blood of immunized animals, as it flowed from the vein, killed pneumococci, they tried to develop a simple and workable way of testing this germicidal power of the whole, unaltered, flowing blood, in which but a small quantity of blood need be used, and the manipulations could be completed before coagulation began. The solution of the problem came from Prof. B. F. Lacy, of the Department of Physics of the Central High School of Philadelphia, and the technique was worked out by Dr. Heist. Dr. Cohen said he therefore termed it the Lacy-Heist method. A capillary glass tube was filled up to a mark with broth culture of pneumococci and then emptied of fluid by touching its tip to a piece of moist gauze. A film containing a certain number of pneumococci remained sticking to the wall of the tube. Blood as it came from the capillary or vein was allowed to flow up the seeded tube to the mark; and it was then sealed and incubated for 24 hours at 37°C, when a drop was blown upon a slide and stained. By using a multiple fan-shaped pipette, such as Wright used, for coagulation, several dilutions of the culture in multiples of 5 or 10 might be used and an approximately quantitative result obtained. If the blood had no bactericidal action, the pneumococci multiplied freely. If it was bactericidal they were killed and no growth resulted. The reaction was sharp, either there was abundant growth, or the bacteria were killed as shown by the absence of colonies upon centrifugalization and plating. This test gave constant results. Pigeons were known to be naturally immune to pneumococcal infections. Their blood destroyed virulent cultures, that flourished in mouse and rabbit blood. On the other hand the blood of mice and rabbits suitably immunized, destroyed the cultures. No bacterial action resulted from the serum of the defibrinated blood either of the naturally immune pigeon, or the inoculated rabbit. Similar observations were made on human blood, showing some men to be naturally immune, others to be susceptible, and others to have acquired immunity by inoculation, or by recovery from pneumonia. Cultures that failed to grow in unimmunized rabbits' blood proved to have lost their virulence. The animals survived large doses. When the virulence was restored by passage through mice and rabbits the bacteria grew in the capillary tubes. The living cultures killed the animal. Such cultures were therefore used as tests for immunity. After inoculation with killed pneumococci by a special method of preparing the vaccine, Dr. Heist was able to produce immunity to Type III as well as to Types I and II and to demonstrate this immunity by the method here described. Even when agglutination tests failed or as in Type III were inapplicable, tests had been made with other organisms, pathogenic and non-pathogenic, including *B. subtilis*, meningococci, and the globoid bodies of poliomyelitis. The authors believed from these uniform results that bacteria which would not grow in the whole blood of an animal, or man, were non-pathogenic for that species or individual, while those that did so grow were pathogenic. They concluded, likewise, that in both natural and artificial immunity, there was in the whole blood a protective force or quality, not to be found in any fraction thereof. They did not know what this was, nor did they know that it was the same in the two instances. Very probably it was not. Tables were shown by Dr. Heist in explanation of the experimental results.

The Rapidity and Persistence of the Action of Digitalis on the Heart.—Dr. G. Canby Robinson of St. Louis, Mo., made this presentation. He said that the study of digitalis was made on patients suffering from a form of cardiac disorder, so influenced by digitalis, that it could be definitely determined when the drug began to take effect, and, in most cases, when its action ceased. Digitalis was administered usually in one large dose in the form of the tincture, and was given by mouth. The dose was determined by the method described by Eggleston, and 0.15 c.c. were given per pound of body weight. In a few instances the dose was reduced on account of certain clinical findings. The cases all showed auricular fibrillation or auricular flutter, as determined by electrocardiograms and in all the ventricular rate was abnormally high. No case was under the influence of digitalis when the massive dose of the drug was given. The doses usually ranged from 15 c.c. to 25 c.c. The effect of digitalis was generally determined by the rate of the ventricles, counted at frequent intervals before and after administration of the drug by auscultation over the heart. The radial pulse rate and the pulse deficit (the difference between the ventricular and radial rates), were also followed and charted. The two cases of auricular flutter were the only exceptions to this procedure. Twenty-six cases were studied and tabulated. In sixteen cases the observations were made at intervals sufficiently frequent after the drug was given to determine accurately the time when the digitalis first became effectual. This was judged by a slowing of the ventricles below the rate seen before the digitalis was given, followed by further slowing and pronounced digitalis effect, or, in two cases, by the disappearance of auricular flutter. In all of these cases the drug became effectual in from two to five hours. The maximum effect of digitalis, as judged by the slowest ventricular rate, was generally seen in from 15 to 26 hours. This space of time was required in 19 cases. In 6 cases the maximum effect occurred in from 6 to 9 hours, and in one case no statement could be made. In 13 cases the heart remained under the influence of digitalis from 4 to 22 days, or an average of 9 days, 8 hours. In one case the effect lasted but one day, while in others no definite duration was determined. A study of these cases demonstrated that a single large dose of the tincture of digitalis, given by mouth, affected the heart soon after administration, and at relatively uniform time, indicating that the drug was well absorbed, at a uniform rate. The maximum effect was usually obtained in about 24 hours and generally continued to be effectual for nearly ten days.

Dr. S. M. White of Minneapolis said that in 1910 he had reported treatments at the clinic of Minneapolis with the interrupted method, as recommended by Eggleston, giving portions of the full dose at intervals. In that way he obtained very marked reduction in the apical rate in auricular fibrillation, with distinct clinical improvement, and in some cases there resulted marked polyuria. They felt that the results of digitalis therapy in auricular fibrillation were extremely gratifying, and that the method might profitably be followed by small tonic doses. In cases studied they found the same period of effectiveness of the digitalis—that is from 5 days to, in one case, 21 days. Evidences could be shown by the inversion of the T-wave, which showed that digitalis was still in effect, but the slowing of the apical rate was somewhat later in duration. In experimental work on animals, using it intravenously, he could get the slowing of the rate in a few minutes.

Dr. Cohen of Philadelphia said that the very interesting paper recalled an epigram of his teacher, Bartholow. He said, "Digitalis acts tomorrow and lasts a week." Now, there was a warning that should be given in the report going out, and that was that there was a long-continued effect of digitalis. He had had a case that came with mitral stenosis, where the patient had been taking digitalis for a long-continued period. He had been told by his physician how to take digitalis, but he had been taking the drug continuously. He had not only fibrillation but digitalis poisoning. He would like to ask Dr. Robinson the dose he used.

Dr. L. A. Conner of New York said he would like Dr. Robinson to say, in estimating the dose, whether in any of his cases he found it large enough to produce unpleasant effects. He did not know that Dr. Robinson recommended this single dosage for continuous use, but it would be interesting to know whether this method of estimating the full dose in practice it did really keep within the safety limits.

Dr. Joseph Erlanger of St. Louis said that Dr. Robinson had said nothing in regard to the mechanism.

Some years ago while he was interested in heart block he had occasion to use in dogs with experimental heart block large doses of digitalis and when the block was complete digitalis had a marked effect on the ventricular rate, increasing it 100 per cent. Now digitalis had other action than upon the heart; it might produce the slowing of the rate by affecting the impulse arising in the auricle and passing into the ventricle, and digitalis was known to depress conductivity where conductivity was somewhat impaired. Was the effect due to depressing the number of impulses passing through the auricle or through the ventricle?

Dr. ROBINSON, in closing, said that in regard to the clinical results he felt that the administration of digitalis in large single doses, according to Eggleston's rule, was a perfectly good procedure if certain restrictions were put upon it. The work of Eggleston had proved excellent. His dosage was very well done and there were very few untoward symptoms, only nausea and sometimes vomiting in about ten per cent. of cases. He was struck by the accuracy of the dosage following Eggleston's methods. In regard to the relation of the T-wave to the persistence of digitalis they had found also that the T-wave remained inverted; but it was interesting that these findings or results coincided with the work at Minneapolis and also with the work of Cohen and Frazer. The dosage was 15 to 25 c.c. As much as 30 c.c. had been given. As to the mechanism, they were convinced that the effect of digitalis in cases of auricular fibrillation was the blocking of the impulses from the auricles to the ventricles. There was no evidence that digitalis influenced the action of the fibrillating auricle. What it did was to put a block in between the impulses so that the ventricle received fewer impulses and caused them to slow and the circulation was improved by the slow ventricular rate.

Observation on Effort Syndrome Among the Drafted Men at a Recruit Depot.—Dr. L. M. WARFIELD of Milwaukee, Wis., read this paper. An attempt was made at the Recruit Depot, Jefferson Barracks, to determine the fitness for service of men presenting the effort syndrome. Acting on the suggestion of Thomas Lewis and his associates, graded exercises were used to separate the men who had only mild symptoms and signs, due to sedentary life and lack of exercise, from those with the true effort syndrome. In the study were brought out (1) the importance of heredity; (2) the almost pathognomonic previous history of precordial pain or distress on slight exertion; (3) the value of graded exercise in sorting the fit from the unfit. A close cooperation between the cardiovascular examiner at the Examining Barracks and the Chief of Medical Service at the Base Hospital, made it possible to place all suspects under hospital care where they were examined carefully by experts and drilled by a non-commissioned drill officer. The effects of exercise were noted, the temperature and pulse being taken every three hours and after exercise. Cases of effort syndrome, of hyperthyroidism, and of other diseases showed no rise of temperature after exercise. Cases of incipient pulmonary tuberculosis, in which the diagnosis was in doubt, on the contrary, showed a rise. This served as an aid in diagnosis of doubtful cases. No case of true effort syndrome improved on graded exercise. All were rejected for general military service.

Dr. HEARD of Pittsburgh said he would like to say a word of a method of treatment which might be applied. Experience had shown the absolute futility of drug treatment and the absolute futility of bed treatment. It was necessary to get them out of bed, and it was necessary to have infrequent examinations and not keep examining them all the time, and also to give them special exercises or drills or games instead of regular drills. There was a convalescent type.

Dr. J. MEAKINS of Montreal said he had studied these cases with Dr. Lewis. Several points had struck him: First, that one paid too much attention to the heart; there was no functional or organic change in the heart, but the reflexes governing the heart were disturbed. This was analogous to what one used to call tynhoid neurasthenia. Not only were these patients mentally disturbed, but also in a psychological sense, and they had at times a bradycardia. It pointed to medical men a moral, and that was in the convalescence from infections diseases it was proved that close to 70 per cent. of these cases either developed their trouble in childhood or after infection or after service training. The patient often said, "I never had this until I had rheumatism or diphtheria and I got up too early." The symptom was the intense exhaustion, the intense fatigue that these men suffered on the least exertion. This was common in convalescence.

Dr. WARFIELD, in closing, said he thought the lesson to be learned was that these symptoms were not symptoms which were unusual because one saw them after every infectious disease. It was a matter of a little longer time in convalescence after the disease was over.

Cardiac Diagnosis in the Light of Experiences with Army Physical Examination.—Dr. L. A. CONNER of New York presented this topic. He said that the most important point gained from this experience was first, in the knowledge of the frequency and the extent of normal variations and, second, the realization of the effort syndrome. He did not think one could say that one knew this syndrome before the war. There had been some advance in the diagnosis of organic valvular disease, and finally syphilitic disease of the heart and arteries had been found to be extremely rare. There were 11,000 heart rejections, and among those only 20 cases of aneurysm. Syphilitic disease did not affect the cardiovascular apparatus between the ages of 21 and 31. In regard to examinations: The position of the apex beat varied widely, and the normal apex beat varied in intensity. Under exercise one got very great variations; the change in the character of the sounds was just as great. In examinations of men under excitement the first sound changed so often that one would be sure it was a pathological sound if one did not have all these normal cases to check up with. In regard to the accidental murmurs, as far as the systolic apical murmurs were concerned, not one in ten represented organic mitral disease. It was perfectly amazing to see how common apical loud systolic murmurs were particularly after exercise and excitement. Some were cardiorespiratory murmurs, and very rarely did they represent actual damage to the mitral valve. In regard to effort syndrome, the fact that one had learned to recognize it and had an acquaintance with it was a fact of very great importance. The importance of its recognition lay in the tendency to mistake it for organic disease. A word about the diagnosis of organic disease; experience had taught the need of greater caution in making the diagnosis. No error was made in aortic regurgitation or in aortic stenosis in finding the disease when it did not exist. In mitral stenosis it was not safe to make the diagnosis without the presence of a definite presystolic murmur. Those who made it on the accentuation of the second pulmonic sound were apt to be mistaken. Many cases of irritable heart simulated mitral stenosis. Mitral insufficiency was certainly a rare disease.

Dr. S. S. COHEN of Philadelphia said he was sorry to differ with Dr. Connor on the question of mitral stenosis. His experience was that that was almost the commonest of lesions and it could be recognized without the presence of the murmur. He was taught diagnosis by DaCosta, who discovered the irritable heart of soldiers. Now the persistence of the signs other than physical signs of mitral stenosis under all conditions differentiated it very sharply from the manner in which the symptoms of irritable heart varied under different conditions, and one of the most constant of these signs before the auricle began to weaken—the prefibrillary stage, was the difference between the effort of the heart and the result in the radial pulse, when taken with the tendency to blood skipping, with the accentuation of the first sound and the jerky action and the sustained rapidity, and the small filling of the pulse. Those made up a physiognomy which he thought an experienced observer was able to call mitral stenosis even in the absence of a murmur.

Dr. W. S. THAYER of Baltimore said the ability to rule out functional murmurs depended on familiarity with the examination of the heart; and young men were too unfamiliar with the examination of the heart. No man could recognize disease of the heart, or the normal heart, unless he had had experience and that experience was theirs to give the students. Teaching of auscultation and percussion in medical schools should be taken hold of in a different way—by small

groups and by the giving of much time by the instructor. Lectures would not do it; books did not teach it. With regard to the relative infrequency of mitral insufficiency, Dr. Conner's conclusion was perfectly true. Loud systolic murmurs heard in the back were exceedingly common and were cardiorespiratory murmurs, often mistaken for cardiac murmurs.

Dr. FRANK BILLINGS of Chicago said he served with the Provost Marshal who was grieved by the number of rejections in the first draft, at which time there were a large number of valvular heart disease rejections. Many different standards were used. As a result of that a new standard was devolved. Dr. Billings said in his experience mitral stenosis was more common in girls. From recent information, there were 5,700,000 registrants called to the colors and examined, and the rejections averaged about 38 per cent. In other words, about 2,000,000 of these men were rejected as unqualified for military service; 340,000 were rejected for tuberculosis.

Dr. H. S. PLUMMER of Rochester, Minn., said that these men, outside of organic cases, that were rejected for effort syndrome, were cases of hysterical neuroses. They greatly simulated hyperthyroidism. The point to make was, to study the man as a whole, not looking to the heart alone. If one talked with the man and learned his mental view, one would learn more than by examination of the heart.

Dr. ALFRED STENGEL of Philadelphia said he feared some of the observations would be translated by the profession at large as observations on cardiac disease on men in general, whereas, as Dr. Conner had pointed out, the fact of the age of the individual made a great difference; and if the profession at large were to take the facts about the effort syndrome and apply them to persons of different ages, they would come to unfortunate conclusions. Dr. Conner brought out the point that they were in *young* soldiers. As regards the syphilitic heart and the period elapsing between the syphilitic infection and the time the trouble in the heart began, there was no time relationship between the two found. The incidence of cardiac trouble in syphilis almost always came along between the ages of 43 and 45, no matter at what age the syphilis was acquired.

Dr. CONNER, in closing, said that before his experience in the war, he would have been inclined to agree with Dr. Cohen in regard to mitral stenosis. He did not think one could make the diagnosis without the presystolic murmur. The profession ought to instruct students in cardiac diagnosis in the painstaking way advocated by Dr. Thayer and raise the standard of cardiac diagnosis.

Some Secondary Characters of the Cardiovascular Function.—Dr. HENRY SEWALL of Denver, Col., made this presentation. He said that the functional efficiency of the circulation was largely determined by activities which cooperated in but did not cause blood movement. The physiological ability of the cardio-vascular mechanism could usually be gauged best, not by a study of the heart directly, but by the play of mechanisms associated with it. The war had strikingly illustrated this postulate in the prominence achieved by the "effort syndrome" or "neuro-cardiac-asthenia." Certain easy clinical tests could elucidate the state of these subsidiary cardio-vascular functions. The first and most valuable of these tests consisted in observation of the influence upon the arterial blood pressures of gravitational resistance to blood flow as developed by change of posture of the body from the recumbent to the standing position. In the normal subject the systolic blood pressure was apt to be slightly higher in the erect posture, the diastolic pressure rose slightly and the pulse pressure usually fell slightly. Perhaps the commonest sign of general asthenia was an abnormal fall of the systolic pressure on assuming the erect posture, due to gravitation of blood to the splanchnic area. But often the disability was shown more by great rise of diastolic than a fall of systolic pressure. This resulted in a corresponding lowering of pulse pressure by which the irrigating capacity of the circulation is measured. When this pulse pressure fell much below 30 mm. Hg. the brain did not get an adequate supply of blood in the erect posture and extraordinary neuromuscular symptoms might develop. There was a second method of studying the associated activities of the circulation which had been nearly completely neglected and which developed interesting facts which could hardly fail to be of functional importance, though their full significance was undetermined. This consisted in observation of the secondary waves of systolic blood pressure which are of at least two kinds: The first of these was the respiratory wave dependent on the fact that the blood pressure was highest in a definite phase of the respiratory movement (usually at the end of expiration) and rhythmically fell as breathing was continued. The depth of this wave might reach 20 to 30 mm. Hg. and depended upon the amplitude of respiratory movement. It was easy to convince oneself, when taking the blood pressure by the auscultatory method, that the sounds of the "first phase" which indicated the maximal blood pressure, appeared first during the expiratory movement. As the cuff pressure was gradually released the pulse sounds spread over more and more of the respiratory cycle. The difference in the stand of the mercury column between its height at the maximal pressure at the end of expiration and maximal pressure at the end of inspiration varied between 0 and 25 to 30 mm. Hg. The difference was commonly about 5 mm. for ordinary respiratory movement. There was another secondary wave of blood pressure which might be recognized by having a period varying from two to any number of respiratory movements. It might be recognized by holding the mercury column with such a degree of cuff tension that a regular succession was heard of "pops" of the first phase of arterial pressure. Very often the sound would rhythmically come and go with a period of a few seconds to many minutes. The depth of the wave might be measured, of course, by dropping the mercury column until the sounds failed to disappear. The wave amplitude might reach easily 10 to 20 mm. Hg. The most obvious explanation of these slow waves would ascribe them to variations of vasomotor tension and bring them in the class first described by Traube. They were found exaggerated in cases of functional instability in the erect posture. It was open to conjecture whether these waves were not due in part to rhythmic variations in the viscosity of the blood.

Dr. JOSEPH ERLANGER of St. Louis said that the change in blood pressure during the respiratory wave was always noticed. Anybody who used the cardiographic method realized that there was one systolic pressure in inspiration which was always low, and another systolic pressure during expiration which was always high. The product of the pulse pressure by number of pulse beats indicated velocity of the blood flow.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago and New York, December 2-19, 1918.

(*Continued from page* 398.)

SURGERY.

Answer any five of the seven questions:

1. Discuss the diagnosis and treatment of hemothorax.
2. Discuss the diagnosis and treatment of perforated duodenal ulcer.
3. Discuss the diagnosis and treatment of renal calculus.
4. Outline the symptoms and surgical management of fractures of the middle third of the femur.
5. Give the diagnostic symptoms and treatment of fracture of base of the skull.
6. Discuss the etiology and treatment of shock.
7. Discuss the surgical aspects of the anaerobic infections.

PATHOLOGY.

Answer five of the following questions:

1. Describe the anatomic changes in blood vessels produced by syphilis.

2. Describe the gross and microscopic changes of tuberculous lymphadenitis as it occurs in cervical lymph nodes.

3. (*a*) Give the criteria of malignancy. (*b*) Name three malignant tumors and give characteristic sites. (*c*) Name three benign tumors and give characteristic sites.

4. (*a*) What is the pathogenesis of malignant endocarditis? (*b*) What are the anatomic alterations that may be found at autopsy in the person dying with it.

5. (*a*) Discuss the etiology of acute poliomyelitis. (*b*) Describe the pathology of this disease.

ANSWERS.

SURGERY.

1. Hemothorax.—"The clinical features are those of internal hemorrhage, with evidence of fluid in the pleural cavity—in the form of dullness, loss of the breath sounds and of vocal fremitus—and of pressure on the lung. The patient becomes extremely restless, constantly changing his position; the breathing is rapid and labored, and the pulse small, quick, and irregular. The effused blood does not coagulate, and in many cases is rapidly reabsorbed. If there is a penetrating wound, blood may escape each time the patient coughs or moves in bed. From faintness or shock at the time of the accident, the blood may not be poured out into the pleural cavity until reaction comes on some hours later, and the sudden onset of symptoms may prove a source of difficulty in diagnosis, suggesting perforation of an abdominal viscus. It sometimes happens that several days after an injury a considerable quantity of serous fluid is poured out into the pleural cavity, and gives rise to symptoms similar to those of hemothorax. The use of an exploring needle, however, serves to distinguish between these conditions.

Treatment: "In all cases in which the thoracic viscera have been injured the patient must be kept absolutely quiet in bed; he is usually most comfortable when propped up in a sitting or reclining position. Steps are taken to combat shock, but stimulation must be employed with discretion on account of the risk of increasing hemorrhage. If the ribs or sternum be fractured, the treatment for these injuries may be employed, unless, as is often the case, the necessary manipulations are contraindicated by the general condition of the patient. The further treatment will depend upon the symptoms present. In many cases of hemothorax no special treatment is required, as the bleeding does not continue long and the effused blood is rapidly reabsorbed; but if the effusion is causing dangerous pressure on the lung, it is advisable to withdraw some of it by aspiration. Care should be taken not to use a strong vacuum in the aspirator, and not to withdraw all the fluid from the chest, lest the rapid expansion of the lung should displace clots or open up the tear in the lung tissue and start the bleeding afresh. When the heart is embarrassed by the fluid in the pleura, great benefit usually follows the withdrawal of ten or twelve ounces of blood from the median basilic vein. When the fluid is not reabsorbed by the end of a fortnight, it may be withdrawn by a fine aspirating needle. The occurrence of septic infection is an indication for incising the pleura, resecting portions of one or more ribs and establishing drainage."—(Thomson and Miles' *Manual of Surgery.*)

2. *Diagnosis of acute perforation of duodenal ulcer:* "There suddenly seizes the patient an excruciating pain, occasionally so fulminant that death quickly follows. He is prostrated, pale and faint, with livid, anxious features and clammy brow. Respirations are short and labored, for deep inspirations increase the agony. The pulse is generally rapid and thready, and muscular rigidity is followed in a few hours by abdominal distention. Extreme tenderness of the whole abdominal surface is usually in evidence. Neither palpation nor percussion is willingly borne by the patient. As the symptoms progress the pulse rate rises, while the pulse character becomes poorer; the abdomen, still rigid, becomes generally distended, the temperature may quickly rise to 102° F. or more, intestinal stasis is absolute, though gas or small amounts of feces may be expelled by enemas, general cyanosis develops, and death may occur in from a few hours to four or five days, should relief not be afforded."—(*Reference Handbook.*)

Treatment of acute perforated duodenal ulcer: In acute cases with rapid escape of much duodenal contents into the general peritoneal cavity, the patient rapidly goes into a state of shock, and any treatment to save life must be quickly applied. The fate of the patient depends much upon the promptness of operation. After twenty-four hours, operation offers little hope; within the first eight hours operation can save the patient without question. Operation should be done as soon as possible; shock is no contraindication. Measures to combat shock should be employed at once with the preparation for operation. No single treatment has greater value than an intravenous infusion. The duodenal region should be exposed as soon as possible. All of the foreign matter should be aspirated or sponged out. Even though widespread, irrigation is undesirable. The opening in the bowel should be closed with a purse-string suture of linen or an infolding suture may be applied. It is well also to place an edge of omentum over the place of suture and hold it there by a few stitches. Drainage may or may not be used. If there has been pus and plastic lymph, drainage should be employed; a pelvic drain is essential. The operation should be rapidly completed.—(From Warbasse's *Surgical Treatment.*)

3. Renal Calculus.—Symptoms consist of pain in the loins, markedly increased by exercise, especially on jolting. The pain may be referred to the thigh, groin, or testicle. The colic is associated with hematuria, and often pyuria exists with frequency of micturition. The kidney may be enlarged and tender on pressure. A large stone may exist without any symptom whatever. The most typical symptom consists in a sudden attack of excruciating and paroxysmal pain shooting down the loin to the bladder and testis. The attack is accompanied by vomiting, faintness, and collapse. Frequent efforts to pass urine are made, but only a scanty amount of blood-stained urine is passed. The pain ceases suddenly when the calculus slips back into the pelvis or reaches the bladder.

Treatment. Palliative: The patient's diet must be regulated so that there is no excess; plenty of fluid should be taken as well as proper exercise. Alkaline purgatives and urotropin should be ordered. Sometimes under this treatment a small stone becomes encysted, but it is unlikely that a stone once formed will be dissolved. Renal colic is treated by hot baths, ½ grain of morphine, or chloroform, to relieve the pain.

Operative treatment is adopted if the above means fail, if a perinephric abscess forms, or a stone is impacted in the ureter. Nephrolithotomy is the ideal operation, but if the kidney is converted into a mere abscess cavity nephrectomy is necessary. Nephrectomy should not be done if it is suspected that the other kidney is also affected.—(*Aids to Surgery.*)

4. *Symptoms of fracture of the middle of the femur.*—History of injury; disability; pain on movement; preternatural mobility; crepitus; shortening of the limb, deformity (simple overriding of fragments, or angular deformity). The lower fragment is drawn upward and inward, and may be either in front of or behind the upper fragment; the ends of the fragments can be felt by the surgeon. The thigh and leg are slightly flexed and, generally, everted.

Treatment: "The limb is carefully washed and, if hairy, shaved. Two long strips of strapping, three inches wide, fixed below to a square piece of board ¼ to ½ inch thick (slightly wider than the ankle opposite the two malleoli), which is known as the stirrup, are heated and pressed against the lower third of the fractured limb. They are here secured by short, thin pieces of strapping 1 to 1½ inches in width, passed in a figure of 8 around the limb above the malleoli and ending just below the fracture; the knee may be left uncovered. It is necessary to see that the pull of the extension is exerted on the femur and not on the knee. Large pads of wool should be introduced between the malleoli and the sides of the strapping, to prevent the skin over these processes becoming chafed. A cord is fixed to the stirrup and passes over a pulley at the end of the bed, and is there secured to a tin can which is filled with shot up to the required weight. If now the

foot of the bed is raised on blocks, extension and counterextension are obtained, the patient's body acting as a counter-extending weight. When the fracture has been manipulated into a good position under an anesthetic (it is always necessary to control the fracture with some splints before the anesthetic is given), the extension apparatus is applied, and Liston's splint is bandaged to the limb. A proper splint of this kind should extend from the axilla to below the foot, and it is secured to the patient in three places: (1) round the thorax, (2) round the limb at seat of fracture, and (3) to the leg and ankle. In securing the thorax it is necessary to take the first turn of the bandage round the splint from within outward, and then round the back of the patient's thorax, the direction of the bandage in this way preventing the natural tendency of the splint to rotate forward. Several turns should be taken round the thorax in order to retain it in position. The remaining bandages should be secured from without inward, in order to check the tendency of the foot and leg to roll outward. In order to prevent the rotation of the limb a method devised by Cheyne and Burghard may be adopted. This consists in securing the limb at the level of the popliteal space to a short splint, 8 by 4 inches, by means of a plaster of Paris bandage. The presence of this splint effectually prevents any rotation, either inward or outward. Special care must be taken to see that the malleoli and the skin over the heel are not subjected to any great pressure. If the fracture is put up in this way it must be kept up for six to eight weeks, and the amount of weight applied to the limb must be varied according to the age of the patient and the tendency to deformity. Roughly half a pound a year will be found to answer most purposes, but if there is much spasm the amount can be increased up to 20 pounds. At the end of six weeks, during which period the limb should have been regularly massaged—this can usually be done without disturbing the extension—the patient should be got up, and some form of retentive apparatus applied. A Thomas's splint is a very valuable form of apparatus, since it enables the patient to get about, and allows of active movements being undertaken, while he himself can hobble about on crutches. If such treatment is not considered advisable, he should be kept in splints for eight weeks, and then allowed to lie in bed without any apparatus on at all, while the limb is regularly massaged, and he should be encouraged to get up for a short time on crutches, gradually exercising the limb, until at the end of about ten weeks he is walking on it as before."—(Pye's *Surgical Handicraft.*) Some surgeons advise immediate operation, and cut down on to the fractured bone and, after reduction, fix the fragments by two or three Lane's plates.

5. *Fracture of base of the skull.* The *Signs* are those of (1) injury to the brain, (2) escape of cranial contents, (3) injury of cranial nerves. (1) *Injury to the brain* may be of the nature of concussion, compression, or laceration. (2) *Escape of cranial contents*, which may be blood, cerebrospinal fluid, or rarely brain itself. 1. *Hemorrhage* manifests itself in various situations, according to the position of the fracture. In the *anterior fossa* the bleeding may be from the nose or into the orbit, or may pass back into the pharynx, be swallowed, and subsequently vomited. The eye may be pushed forward and pulsate if the cavernous sinus be ruptured. In the *middle fossa* blood usually runs from the ears; but slight bleeding from the ear may be caused by minor injuries, such as rupture of the membrana tympani, tearing of the lining of the auditory canal, and fracture of the tympanic bone. In the *posterior fossa* a hematoma may form behind the mastoid process. 2. The escape of *cerebrospinal fluid* is a certain sign that a fracture communicates with the subdural space. It may appear in the same situations as hemorrhage, but is usually found escaping from the ear owing to fracture of the petrous bone. The fluid is limpid, specific gravity 1005, with no albumin, but containing pyrocatechin, which gives the same reaction as sugar with Fehling's solution. The amount which escapes may be small or very large, but as a rule it soon ceases. (3) *Injuries to the cranial nerves* vary according to the site of fracture. That most commonly involved is the facial, in the aqueductus Fallopii, and the paralysis may come on immediately from rupture, or after two or three weeks from the pressure of callus.

Treatment: The chief aim of treatment is to prevent sepsis. The ear must be mopped out with an antiseptic, and then kept covered with an antiseptic dressing, as if it were a wound. The patient must then be kept quiet, the bowels opened with a purge, and an icebag applied to the head. The diet should be low, and a return to active life not permitted for six weeks. If septic meningitis occurs the patient is bound to die.—(From *Aids to Surgery*.)

6. *Etiology of shocks:* "The explanation of shock usually accepted, largely on the authority of Crile and Mummery, is that the paralysis or exhaustion of the vasomotor center in the medulla results in a lessening of the vascular tone, particularly that of the arteries, and a marked fall in the blood pressure. Most of the blood leaves the arteries and collects in the large venous trunks, especially those of the abdomen, and there is thus produced an anemia of the brain and of the superficial parts of the body. At the same time the right side of the heart becomes overloaded and impeded in its action. According to J. D. Malcolm the disturbance of the vasomotor center results, not in dilatation, but in contraction of the arteries. At first the superficial vessels are constricted, and if the exciting cause is kept up this condition spreads back to the larger vessels, so that the blood is driven out into the tissues and back into the abdominal veins."—(Thomson and Miles' *Surgery.*)

Treatment of shock: Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermically, may be necessary for the relief of pain. Adrenalin solution is administered into the arterial system.

In surgical operations *shock may be largely prevented* by reassuring nervous patients, keeping the patient warm, the avoidance of the excessive catharsis, and semi-starvation that often prevail before operations, the administration of strychnine and atropine before operation, the avoidance of delay and undue exposure or handling of parts during the operation, prompt checking of hemorrhage, and by using the utmost gentleness. With a view to preventing the passage of exciting afferent impulses, Crile advocates "blocking" of the nerves by the injection of a 1 per cent. solution of eucaine into their substance on the proximal side of the field of operation.

7. *Surgical aspect of the anerobic infections:* The lesions resulting from tetanus are the chief examples in civil life. But the various forms of infection causing gas gangrene are more common in war surgery. The anerobes causing these infections have an ideal environment in many war wounds; there is much dead and devitalized tissue, a large number of organisms, numerous infected pockets, and other conditions which aid anerobiosis. The proteolytic action of these microorganisms and the avidity with which the muscles are attacked render them particularly obnoxious. Their toxic action spreads rapidly, surrounding tissues are attacked, toxemia and septicemia may develop, and in many cases they are aided by the ordinary aerobic infective agents. Only early, systematic and thorough treatment is of service; all devitalized and infected tissue must be excised; Carrel's tubes, antiseptic lotions and pastes, serums and vaccines have all been used in addition to prompt surgical measures.

PATHOLOGY

1. "*Syphilis* may involve the blood-vessels in a variety of ways. No doubt, syphilitic infection is the most potent cause in the production of arteriosclerosis, but more specific involvement of the vessels occurs. Thus in areas of spyhilitic infiltration and induration or adjoining gummata, the blood-vessels present noteworthy changes. The intima and the adventitia, but particularly the former, undergo great hyperplasia, and the lumen of the vessel may be almost obliterated. The changes are first noted in the intima, where large numbers of epithelioidal cells are formed, while, later, infiltration of round cells is observed. The adventitia is similarly, but less extensively, affected. There is no

histologic or macroscopic feature by which the syphilitic nature of the disease can be positively asserted."—(Stengle's *Pathology.*)

2. *Tuberculous lymphadenitis:* "The first visible change is the formation of small grayish nodules in the gland, and sometimes the eruption of these is attended with hyperemia and inflammation. Later, these tubercles increase in size and undergo caseous changes, and eventually the entire gland may be converted into a cheesy mass, which may liquefy and not rarely discharges through the ruptured capsule. Microscopically, the first appearance is that of gray tubercles containing giant-cells and epithelioid cells, surrounded by a zone of round cells. Later, the characteristic appearances of hyaline transformation and of caseation are observed. Sometimes the glands in tuberculosis become enlarged and harder than normal, and present areas of grayish color, but do not tend so markedly to undergo necrosis. In these instances the microscopic examination presents foci composed for the most part of epithelioid cells, and much less abundant in round cells than are tuberculous tissues as a rule."—(Stengel's *Pathology.*)

3. *The criteria of malignancy*, are: The tumor is not encapsulated, it grows rapidly, it produces metastatic growths, it causes cachexia and progresses towards a fatal termination, it tends to recur after removal.

Three malignant tumors: (1) *Sarcoma*, found in skin, subcutaneous tissue, facsia, periosteum, uterus and ovary; (2) *Carcinoma*, found in stomach, uterus, breast, rectum, ovary and testicle; (3) *Epithelioma*, found in skin (especially where it joins the mucous membrane), lips, mouth, esophagus, vagina, cervix uteri, and stomach.

Three benign tumors: (1) *Fibroma*, found in uterus, subcutaneous tissues, periosteum, ovary, testicle, and breast; (2) *Lipoma*, found in subcutaneous tissue (of shoulders, back of neck), and in gastro-intestinal tract; (3) *Chondroma*, found in bone and cartilage, and in parotid, testicle, ovary and breast.

4. MALIGNANT ENDOCARDITIS. *Pathogenesis:* "Diplococcus of Poynton and Paine, streptococcus pyogenes, staphylococcus pyogenes aureus, diplococcus pneumoniæ, gonococcus, and streptococcus viridans are the chief bacteria found; but others have also been observed in this condition. Their etiological significance is not settled. *Gross changes:* In the simple form there will be found a cloudiness, followed by edematous thickening of the valvular endocardium, superficial erosions, and the formation of small granulations; deposits of layers of fibrin and corpuscles from the blood, the whole process resulting in the formation of small warty vegetations. These vegetations are most marked at a slight distance from the free borders of the valves—*i.e.*, those parts which come into opposition during closure. In course of time they are transformed into fibrous tissue. According to Poynton and Paine, the infective organisms are conveyed to the base of the valves by the capillaries, and thence pass to the subendothelial tissues by the minute nutrient channels in the valvular substance; others hold that the organisms are derived from the blood circulating over the surface of the valves. In the malignant form the initial changes are similar, but there are some important differences, inasmuch as ulcerations may completely replace the vegetations. The differences are: (1) The vegetations when present are larger and fungating. (2) The underlying tissues are necrotic and show loss of substance and round-celled infiltration. (3) They contain masses of micrococci, while in simple endocarditis the organisms are scanty. The two forms cannot be distinguished by the organisms producing them; either simple or malignant endocarditis may arise from a pyogenic infection. (4) When the vegetations become detached they form *septic* emboli, giving rise to metastatic abscesses. (5) The ulcerative process causes great destruction of the valves, and may even lead to perforation of the curtains. (6) The subsequent or permanent changes in the valves, if the patient survive, are much more marked. (7) If the vegetation touches the mural endocardium as it flaps to and fro, the part touched becomes affected by contact. *Microscopical Changes.*—The vegetations are seen to be nonvascular, structureless masses composed of fibrin and fused blood-plates; bacteria may or may not be present. If the inflammation is severe on or near the mitral valve it may spread to the chordæ tendineæ and papillary muscles. Hyaline degeneration, coagulation necrosis, or round cell infiltration may be found in the endocardium."—(Wheeler and Jack's *Handbook of Medicine.*)

5. *Acute poliomyelitis. Etiology*: It is caused by a minute, filterable microorganism, which chiefly attacks the mucous membranes of the nose and throat, and leaves the infected body by the secretions of the nose, throat and intestines. From the mucous membrane of the nose and throat the virus travels by way of the lymphatics to the brain and spinal cord.

Pathology: "The lesions consist of inflammation, softening, and hemorrhage, in mild cases, more or less limited to the anterior horns of the spinal cord, and leading to marked degeneration of the motor ganglion cells, the lesions, even in mild cases, however, may be more widespread and may be associated with lymphocytic infiltration of the pia-arachnoid. Analogous lesions may occur in the medulla, pons, and gray matter of the cerebrum. In severe cases the lesions are those of diffuse myelitis and encephalitis, with more or less meningitis. Flexner and Lewis have found the virus in the central nervous system, the cerebrospinal fluid, and mesenteric lymph nodes. After the disease has run its course, the affected portion of the cord is found lessened in size; the anterior horns are greatly atrophied and contain few if any ganglion cells; the corresponding motor nerve roots are atrophied; and the muscles supplied thereby are atrophic, sclerotic, and perhaps fatty. The lower motor neuron, therefore, bears the brunt of the infection."—Kelly's *Practice of Medicine.*)

THERAPEUTICS AND GASTROINTESTINAL DISORDERS.*

BY DOUGLAS VANDERHOOF, A.M., M.D.,

RICHMOND, VA.

PROFESSOR OF MEDICINE IN THE MEDICAL COLLEGE OF VIRGINIA.

IN the pleasant task of addressing you today, I have chosen as my subject the relation of therapeutics to gastrointestinal disorders. As in every correct application of therapeutic endeavor, however, the consideration of this broad field involves primarily an analysis of the causative factors and a correct interpretation of their clinical manifestations.

The term "indigestion," so frequently applied by the patient to a great variety of ailments, is becoming obsolete in medical literature. This is due, of course, to the fact that indigestion is in most instances only a symptom and not a disease. Yet indigestion is one of the most frequent complaints that brings the patient to the doctor. For this reason, I shall make free use of this term to designate the complaint of patients with symptoms referable to the stomach, bowels, and abdomen in general.

It is distinctly unfortunate, as I have emphasized in a previous address,[1] that the physician who is particularly interested in gastrointestinal disorders soon becomes regarded as a "stomach specialist." Such a designation is infelicitous in that it implies too narrow and incomprehensive a field of work. A case of "long-standing indigestion" will often require all the ingenuity of a competent internist and his Roentgenologist in the process of diagnosis, to be supplemented in its treatment by the surgeon, orthopedist, dentist, oculist, or neurologist.

The Causes of Indigestion.—The attempt to classify the causes of indigestion has been a matter of some difficulty in the past. As a result, a purely symptomatic nomenclature has obtained, which still appears in most textbooks on the subject. Several years ago I made a clinical study[2] based on the histories of one thousand consecutive private patients who presented themselves for the relief of chronic or recurring indigestion. The series embraced only those patients whose chief complaint was attributed to some disturbance of digestion, such as "stomach trouble," dyspepsia, abdominal pain, flatulence, vomiting, etc., and entirely excluded patients complaining of other symptoms who were found on examination to have some lesion of the gastrointestinal tract. The result of this study was so interesting that I have recently added an additional one thousand cases and have tabulated the clinical diagnoses in these two thousand consecutive patients as shown in the accompanying chart.

CAUSES OF "INDIGESTION"—ANALYSIS OF 2,000 CASES.

		Cases	Per Cent
1.	Chronic appendicitis	436	21.8
2.	Chronic cholecystitis	224	11.2
3.	Neuroses	218	10.9
4.	Peptic ulcer	206	10.3
5.	Kidneys, affections of	137	6.8
6.	Achylia gastrica (uncomplicated)	81	4.0
7.	Visceroptosis	69	3.4
8.	Lungs, affections of	60	3.0
9.	Heart, affections of	50	2.5
10.	Cancer of stomach	46	2.3
11.	Blood and ductless glands, affections of	44	2.2
12.	Enterospasm (mucous colitis)	40	2.0
13.	Peritoneal adhesions	38	1.9
14.	Female pelvic organs, affections of	35	1.7
15.	Eyes, affections of	32	1.6
16.	Migraine	26	1.3
17.	Central nervous system, organic disease of	22	1.1
18.	Cancer of intestine	21	1.0
19.	Infectious diseases	19	0.9
20.	Liver, affections of	18	0.9
21.	Ears, affections of	16	0.8
22.	Enterogenous toxemia	11	0.5
23.	Miscellaneous conditions	114	5.7
24.	Diagnosis not made	37	1.8

Each patient in this series has received thorough study embracing a careful history, complete physical examination, and the necessary laboratory analyses, including as a routine one or more gastric analyses, urine examination, and differential blood count, with hemoglobin determination. In the second half of the series the fractional method of gastric analysis has been employed and routine Wassermann tests of the blood serum have been done. Advantage has been taken of skillful *x*-ray studies, and much helpful advice has been secured in free and unconstrained consultations with my surgical colleagues, in whose operating rooms I have seen many of these patients treated surgically.

Of course, I am aware that the value of such a tabulation of diagnoses is open to question, and that it is dependent upon the constructive reasoning that supplements a careful and complete study of each individual patient. In addition to the possible margin of error, certain patients presented more than one lesion that might have acted as a reflex cause of indigestion. In such instances I have tabulated, according to my discretion, the one that seemed most likely to be responsible.

The deductions to be drawn from this table, granting that the diagnoses are essentially correct, are most instructive. These figures show that chronic appendicitis heads the list of causes of chronic or recurring indigestion, and accounts for

*President's address, delivered at the twentieth annual meeting of the American Therapeutic Society, held at Atlantic City, N. J., June 6 and 7, 1919. For discussion see page 519.

about one-fifth of all cases. In like manner, chronic inflammation of the appendix or of the gallbladder is responsible for one out of every three instances (33 per cent.) of chronic or recurring indigestion. Approximately 10 per cent. of cases are due to peptic ulcer, while functional disturbances, and affections of the kidneys and heart, each account for another 10 per cent. Cancer of the stomach and intestines shows an incidence of less than four per cent. A word of explanation is in order regarding the frequency of achylia cases (four per cent.). Gastric anacidity is found in about one-sixth of all patients subjected to gastric analysis as shown by me in a previous article.[3] Certain of my achylia cases do not appear in the table because, as is so often the case, the patients did not complain of indigestion, but of other symptoms, such as weakness, nervousness, etc., or had an unexplained anemia; while in many other instances of achylia the cause of the patient's trouble was found to be cholecystitis, malignant disease, etc., and so indexed. The four per cent. incidence refers to "dyspeptics" with uncomplicated gastric anacidity.

Included under miscellaneous conditions in the table are such diseases as pellagra, amebic dysentery and malaria, together with focal infections of the tonsils and teeth, and instances of cyclic vomiting, intestinal parasites, cardiospasm, diverticulitis, peritoneal tuberculosis, cancer of pancreas or esophagus, retroperitoneal sarcoma, hypertrophic spondylitis, etc.

The Symptoms of Indigestion.—The chief symptoms presented by the patient with chronic or recurring indigestion are comparatively few and limited. They may be conveniently discussed under the following heads:

1. Loss of Appetite: Distaste for food or a disinclination to eat is a most important sign of impaired health in animals (dogs, horses, etc.), as well as in infants and young children, and the return of appetite is an indication of restoration of health. In human adults loss of appetite is also significant, but its importance as a symptom is diminished by the fact that man resorts to so many artificial aids to his appetite. Carlson has shown that there may be absence of the normal gastric hunger contractions even in cases where no organic lesion in the stomach can be demonstrated.

Anorexia indicates that there is something wrong in the economy, as James Mackenzie expresses it, or is an indication that all is not well. It arises from a variety of unrelated causes and is not incompatible with a perfectly good digestion. Examination may reveal the cause and the appetite return when the cause is removed.

2. Coated Tongue: As a symptom of indigestion, the coated tongue gives no evidence of real value, and its appearance is certainly subordinate in importance to the condition of the teeth, tonsils, and pharyngeal wall. The tongue is in no sense the mirror of the stomach, and there is no direct relation between the coating of the tongue and affections of the stomach. I know of only one condition of the tongue from which any forecast may be made of the gastric secretions, and that is the bald, red, and glazed tongue often seen in cases of gastric anacidity.

As a matter of interest, I made a review[4] several years ago of the histories of 1500 consecutive patients on whom gastric analyses were made and noted the accompanying description of the tongue. The findings were tabulated as follows:

Gastric Analysis.	Tongue Clean, per Cent.	Tongue Coated, per Cent.
Anacidity	35.0	65.0
Subacidity	35.9	64.1
Normacidity	35.0	65.0
Hyperacidity	27.3	72.7

The interesting fact is thus brought out that the proportion of clean and coated tongues is independent of the state of the gastric juices. The slightly higher percentage of coated tongues in hyperacidity cases probably has no significance, and it is believed that a larger series of patients would show about the same proportion of coated tongues in both hypoacidity and hyperacidity.

Investigations by Mueller (1898) and Fuchs (1900) showed that 62 per cent. of apparently healthy people had coated tongues. Hence the further interesting fact is elicited that the appearance of the tongue in patients requiring gastric study is not essentially different from that in healthy individuals.

The chief causes of a pronounced coating of the tongue are three: (*a*) Nasal obstruction with mouth breathing. The mouth is not intended as a respiratory passage, and any interference with the normal manner of breathing brings about an artificial condition of which one symptom is the furred or coated tongue. Under this cause falls the fever patient and also the habitual smoker.

(*b*) Absence of friction, as noted in patients on liquid diet, etc. The posterior third of the tongue is constantly found coated in many normal individuals, and this is attributed by Mackenzie to the fact that in these cases the palate is high and arched so that the tongue does not come into contact with the roof of the mouth.

(*c*) Perversion of salivary secretion. With overaction of the submaxillary and sublingual glands, the secretions of the mouth are thick and mucilaginous, whereas the parotid saliva is thin and watery. This perversion of the salivary secretions, which I have explained in detail in the article referred to, is probably the most common cause of coated tongue in neurotic individuals.

3. Nausea and Vomiting: As a symptom of chronic stomach affections, nausea and vomiting are relatively infrequent and of very varied significance. These two symptoms occur under the following diversified conditions:

(*a*) Toxic states; as seen at the onset of infectious diseases, in pregnancy, migraine, hyperthyroidism, acidosis, catarrhal jaundice, etc.

(*b*) Reflex disturbances from the eyes, internal ear, pain, and emotions.

(*c*) Pharyngeal irritation, seen in the morning vomiting of alcoholics and smokers, and especially in patients with pulmonary tuberculosis.

(*d*) Habit vomiting, seen in individuals who have acquired the trick of emptying the stomach on the slightest provocation.

(*e*) Brain and spinal cord lesions, such as tumors, injuries, tabetic crises, etc.

(*f*) Gastrointestinal diseases. These are comparatively infrequent causes of nausea and vomiting except in instances of pyloric spasm or stenosis, intestinal obstruction, and acute inflammatory conditions within the abdomen.

Vomiting of blood, pure and in quantity, almost always indicates either peptic ulcer or some obstruction of the portal circulation with esophageal or gastric varices.

4. Pyrosis and Sour Stomach: In discussing these symptoms we must remember that the normal stomach content is exceedingly sour. The consciousness of this sourness on the part of the patient indicates pylorospasm with or without regurgitation into the esophagus. Hyperacidity alone is not the cause of "heartburn" and "sour stomach," as it can be proven that the mucous membrane of the stomach is insensitive to greatly increased amounts of hydrochloric acid. Pyrosis is not uncommon in achylia gastrica and has been complained of in 17 per cent. of my anacidity cases. While the cause is obscure, I am inclined to attribute it to the accompanying gastritis. It is relieved by the administration of full doses of hydrochloric acid with the meals.

5. Flatulence: One of the most common complaints of patients suffering from indigestion is belching or eructation of gas. These patients frequently say that everything they eat "turns to gas," and they occasionally volunteer the information that they are suffering from "*gas*tritis"! They generally believe that the condition is due to fermentation of food in the stomach and not infrequently they have been treated on the basis of such an occurrence.

In the light of the many investigations that have been made in the study of flatulence, it has been abundantly shown that most of the gas in such cases is really atmospheric air that has been swallowed. Fermentation may be an added factor in instances of pronounced stasis, but can give rise to only a definite and small quantity of gas. A third factor is the likely possibility of so-called "alimentary respiration" with the actual secretion of carbon dioxide by the gastric and intestinal mucosa. An excellent discussion of this subject in general is to be found in a recent article of Kantor[5] to which is added an extensive bibliography.

Air-swallowing, or aerophagia, is seen in its most striking form in hysterical subjects. In such cases enormous volumes of air may be expelled. Instances are on record of patients who have belched over 5,000 times in 24 hours, and the amount of air eructated has been measured and found to exceed 200 liters. It is evident, in examples of this kind, that the quantity of gas expelled is many times in excess of that which could possibly be produced by any conceivable process of fermentation. Furthermore, the gas eructated in such cases has been collected and analyzed and shown to consist of oxygen and nitrogen in about the proportion found in atmospheric air, with the admixture of a small quantity of carbon dioxide. This latter gas may represent an actual secretion of the gastric mucosa or may arise in part from the decomposition of the carbonates in the food or in the swallowed saliva. Carbon dioxide is produced in quantity, of course, when a patient with a normally acid gastric juice takes a full dose of bicarbonate of soda.

Aerophagia is entirely independent of the character of the gastric secretions, and may occur as a pure neurosis, or may be a symptom accompanying many and varied organic diseases. Some years ago I showed that air-swallowing occurs relatively as frequently in patients with gastric subacidity as in those with an excess of hydrochloric acid, and that it is just as much a feature of organic disease as purely functional ones.[6]

To the unfortunate patient afflicted with flatulency, the condition is real and apt to be distressing. To the physician making the diagnosis, flatulency is a symptom of minor importance. The relief of the condition demands the removal of the cause, whether it be gallstones, an error of refraction, or simply a bad habit.

6. The Significance of Mucus: The secretion of increased amounts of mucus by the stomach, or by any mucous membrane in the body, is frequently attributed, in a most complacent manner, to catarrh. This unfortunate term is defined (Dorland) as an inflammation of a mucous membrane with a free discharge. According to the newer gastrointestinal studies, the production of increased quantities of mucus does not indicate in any way an inflammatory condition of the mucosa but rather a nicely adapted protective measure.

As an experimental proof one can best refer to one of the classic experiments of Pawlow, which is summed up in the following quotation:

"When powerfully acting substances, such as absolute alcohol, a 0.2 per cent. sublimate solution, a 10 per cent. solution of nitrate of silver, or a strong emulsion of oil of mustard, were introduced for a few minutes into the stomach (of the experimental animal), they produced a more or less considerable, indeed, in many cases an enormous secretion of mucus. One might think this was a serious pathological condition, an acute mucous catarrh. Is it, however, a condition of disease? In extreme cases, more than one hundred times the normal amount of mucus was secreted by the irritated surface. At times, only mucus instead of juice was obtained during the whole period of secretion, and yet I ask again, is it a morbid state? Often, after the lapse of an hour or two, the more or less copious secretion of mucus, which immediately appeared upon the application of the irritating substance, had wholly exhausted itself; or an enormous flow of mucus, which on the day of the experiment had completely suppressed the normal secretion of gastric juice, may, on the next day, to one's utter astonishment, have disappeared without leaving a trace behind. The contrast between the intensity of the phenomenon and its short duration is really striking. One cannot resist the idea that in the cases described no morbid condition had as yet been established, but rather that the pathogenic influences had been successfully battled with and conquered before our eyes. Has not the true physiological function of the surface epithelium of the stomach been here revealed—a function of which we could form no adequate conception in the normal course of affairs? By virtue of its wonderful power of secretion, a large quantity of mucous fluid is poured out which dilutes the noxious substance, or forms chemical combinations with it, and drives it away

at the same time from the stomach wall. The surface epithelium thus wards off the danger which threatens the more important elements of the mucous membrane beneath. That this explanation is correct is also shown by the fact that the peptic glands remain absolutely at rest, in striking contrast to the extreme activity of the surface epithelium."[3]

Mucus in the gastric contents is observed most frequently in certain cases of achylia and in instances of alcoholism. The daily introduction of food into the achylous stomach, where it remains unchanged and undigested until it passes into the duodenum, would eventually prove distinctly irritating to the gastric mucosa did it not defend itself by the outpouring of mucus. In a similar way, the drinking of inordinate amounts of whisky provokes an abundant flow of mucus in the stomach, thus giving rise to the clinical picture of so-called alcoholic gastritis.

Mucus in the stools does not denote inflammation but rather a protective reaction against irritants, chiefly cathartics. It is associated almost invariably with a spastic contraction of the intestinal walls. So-called mucous colitis is not in any sense an inflammatory lesion but in reality a severe spastic constipation, or enterospasm, often amenable to observation by the sigmoidoscope or by *x*-ray studies of the colon. The first essential in the treatment of enterospasm, as I have pointed out elsewhere,[4] is rest for the bowels. This can be secured only by the absolute discontinuance of strong purgatives and all forms of intestinal irrigations. When this is supplemented by a proper full diet, plus belladonna and mineral oil, it is surprising how quickly the condition can be controlled.

7. Visceral Pain: The cause of pain in visceral disease is too large, and perhaps too controversial, a subject to discuss here. If, however, one follows the teaching of Mackenzie and others, and appreciates the fact that effective stimulation of any part of a nerve fiber, from the periphery to the brain, elicits prompt evidence of its peculiar function—*e.g.* the optic nerve, the auditory nerve, etc.—the cause of pain in visceral disease is not so difficult to understand.

"In the normal processes of life a succession of stimuli is continually passing from the viscera, by the afferent nerves, to the spinal cord. Here they react upon the efferent nerves which supply muscles, blood-vessels and other structures. Under conditions of health these processes are so conducted that they give rise to no appreciable sensation. If, however, on account of a morbid state in any viscus, an increased stimulus passes by the afferent nerves to the spinal cord, this abnormal stimulus may be sufficient to affect neighboring nerve cells. These cells then react according to their function, a sensory cell by producing pain, a motor cell by the contraction of certain muscles, a secretory nerve by increased flow of its peculiar secretion, and so forth."[5]

Then again, it has been shown that in visceral disease certain areas in the spinal cord become so irritable that stimuli from the viscera give rise to an exaggerated response. "The irritable focus in the cord is of great frequency in stomach affections. When pain occurs after food it must not be assumed that there is an inflammation of the mucous membrane, or that the stomach itself is hypersensitive. The ingestion of food under normal circumstances is accompanied by reflex processes which are not perceived, and pain merely indicates that there is an irritable focus in the cord through which these reflex processes pass. The lesion inducing the irritable focus in the cord may not necessarily be a stomach lesion at all, but may arise from a neighboring organ whose reflex center in the spinal cord is in close proximity to that of the stomach." Thus in gallstone colic, or in acute inflammation of the appendix, the afferent stimulus may be so violent as to invade the stomach area in the cord, and in chronic inflammations of these same organs this invasion of the area in the cord gives rise to the various train of symptoms referred so constantly to the stomach.

Treatment of Indigestion.—As stated in my introductory remarks, the term "indigestion" is a broad one and covers a variety of conditions. Throughout this article I have used it intentionally to include the complaints of patients referable to the stomach and intestines.

The first thing to consider in dealing with indigestion is that we are called upon to treat a symptom, *e.g.* pain, vomiting, flatulence, etc. To be successful, however, we must not treat the symptom as such, but find and eradicate the underlying cause. Simply relieving the symptoms rarely cures chronic or recurring indigestion. The cause of the symptoms must be determined and explained in a proper way, and it should be realized that it is not what one eats that gives rise to indigestion but the state of the gastric nerves when one eats. The popular idea of restricting the diet of every patient with indigestion is not only a fallacy, but may be largely responsible for the continuation of the symptoms. Drugs, of course, have their place (1) in relieving symptoms, as witness the value of belladonna and alkalies in pylorospasm, and (2) in removing the cause, *e.g.* digitalis in chronic passive congestion of the stomach and liver in myocardial insufficiency. Psychotherapy cures some cases, proper eye-glasses others, glandular therapy still others. The important part played by competent surgery, when based on proper study and interpretation of symptoms, is one of the greatest advances of recent years in the treatment of many gastrointestinal disorders.

In conclusion, may I again call attention to the table in the early part of this article, wherein are compiled the more common causes of chronic or recurring indigestion in the order of their frequency. A brief consideration of such a tabulation suggests at once the treatment to be adopted in most instances.

PROFESSIONAL BUILDING.

PERIPHERAL IRRITATIONS AND THEIR REMOTE CONSEQUENCES.*

BY ROBERT T. MORRIS, M.D.,

NEW YORK.

A FAMILIAR example of peripheral irritation occurs when a child pushes a bean into its ear and then suffers from vertigo and vomiting. The "reflex" disturbance occurs through the cerebral center. Another object lesson occurs with some cases of loose kidney. The patient may suffer from gastric crises and general disturbance of the gastroenteric function because of the afferent impulse sent from the loose kidney to the spinal cord center with efferent response, involving various groups of abdominal and sympathetic nerves. Accepting the fact that peripheral irritation, like that from a bean in the ear or from loose kidney or from a nonerupted molar tooth, or from fibroid appendix, or from pelvic adhesions, may produce distant demonstration, we must elaborate a bit and inquire about the class of patients who make response to peripheral irritation.

A strong man, full blooded, maintaining a good nervous balance in the presence of various kinds of disturbing impulse, may not suffer at all from peripheral irritation which might excite a high degree of response on the part of another patient with narrow costal angles, high arched palate, gunstock scapula, and other stigmata of arrested development. The latter represents the patient who becomes neurasthenic because of inherited tendency toward deficient nervous control. Another step in concatenation includes a third set of consequences from peripheral irritation. The second set of consequences will relate to overstimulation of autonomic and sympathetic ganglia, including cord and brain centers. Under the influence of this sort of over-stimulation, there is derangement of function of the gastroenteric tract, so that food, instead of undergoing complete digestion, is subjected to various fermentative or putrefactive changes, and the patient is poisoned, not only directly by toxins, but by faulty elimination of waste products. This poisoning, in turn, may disturb the endocrine system and may disturb the endocrine glands in such a way that their enzymes produce a special set of morbid phenomena. We may have symptoms in one patient like those of mental derangement, such as melancholia, manic depressive insanity, or cyclothymia as the end result of a peripheral irritation which would not at all disturb another individual carrying the same kind of objective primary defect.

This brings me to a point which I wish to make in relation to care in diagnosis. Symptomatic treatment is so largely unsatisfactory and elaborate diagnosis so seldom made according to the old regime that I believe we are about to enter upon a most important stage in the development of the history of medicine, namely, team work in diagnosis. A patient is to be sent to various specialists, each one of whom will likely enough claim the patient for his own, but he is not to have that patient. He is merely to present a report upon diagnosis and allow the physician in charge of the case to exercise judicial faculty, after having made up a brief, as the lawyers would call it, from the reports of the various specialists.

In order to simplify our proposition, let us confine ourselves to just one of the kinds of peripheral irritation which I have mentioned—that belonging to loose kidney. I frequently come in contact with surgeons who wish to operate upon almost every patient who presents a case of loose kidney. Quite as frequently we find physicians who do not believe in having the operation done at all. What is to become of the patient who gets into the hands of either one of these kinds of specialists who are supposed to represent knowledge and wisdom while acting in the capacity of guide, counsellor and friend for the patient? The situation is one calling for a better physician than the one whom a patient is likely to find readily. It is an important matter for the physician to make such careful analysis of the symptomatology in any given case that he arrives by deduction at the right conclusion in relation to the significance and value of any one symptom in the case. He is to decide if one particular loose kidney requires fixation, while another loose kidney calls for no operative work, and, in fact, for no attention of any sort. He may begin from the fourth set of symptoms, or the third set of symptoms, or the second set of symptoms and arrive at the right conclusion concerning the fundamental factor in the patient's ills.

It is said that seven-tenths of all human action is based upon misconception. Almost every man will say that he doubts if that estimate belongs to him, but he can see where it belongs to the other fellow. In such a simple matter as correct interpretation of his own motives by members of his own family, he may find that this estimate of psychologists is not far wrong. When he goes a step further away and enters into the complex questions relating to the symptomatology of his patients, he must be ever alert in avoidance of that sort of misconception which would lead him to do wrong things for his patient. There is no part of the field of medicine in which I personally see more mistakes made by my colleagues than in this matter of peripheral irritations and their remote consequences.

616 MADISON AVENUE.

*A paper read at the annual meeting of the American Therapeutic Society, June 6 and 7, 1919. For discussion (see page 521).

Oil Acne.—An affection known literally in Spain as "boton de aceite" is said to prevail as an occupational disease in certain metallurgical works where grease is extensively used. Like tar acne, chloric acne, etc., it appears to be due largely to obstruction of the pilosebaceous follicles. It is largely limited to the backs of the forearms. Papules are formed of various size in the center of which is seen a black dot. Considerable itching is present. It is evident that plentiful use of soap should prevent this affection and this course also is successful in curing it in conjunction with massage. —*La Medicina Ibera.*

SOME OBSERVATIONS ON PELLAGRA.

By EDWARD HUNTINGTON WILLIAMS, M.D.,

AND

GEORGE G. HUNTER, M.D.,

LOS ANGELES.

A LITTLE over four years ago we reported our observations on cases of pellagra occurring in this vicinity. At that time we pointed out that most of our patients, unlike the majority of those reported from the pellagra zone proper, were persons in comfortable circumstances. In the present paper we wish again to emphasize this point, and also call attention to certain other anomalies presented by the sporadic cases observed here.

It is evident that pellagra is no longer a regional disease; and its importance may be judged by some statistics published recently by the Metropolitan Life Insurance Company. Thus it is asserted that: "The death rate of 4.3 per 100,000 exposed is . . . higher than for . . . erysipelas, malaria, Potts' disease, general tuberculosis, the deadly epidemic cerebrospinal fever, epilepsy, and gallstones." Moreover, the disease seems to be increasing by stretching its tentacles into regions remote from the original pellagra zone.

Practically all of our cases developed profound mental symptoms, which terminated either in death or permanent dementia. This suggests that the disease, as we see it here, is of a virulent, chronic type that tends to produce mental deterioration somewhat more frequently than is the case in the Southern States. At any rate, the high incidence of mental cases cannot be fully explained on the ground that such cases would be the ones more likely to come under our observation, since several of our cases were seen before any mental symptoms developed.

The three following cases may be taken as representative of the type of pellagrins observed here:

CASE I.—Mrs. H., a married woman, 37 years old, who has been living in or near Los Angeles for several years, was first seen on July 2, 1914. Has one healthy child seven years old, and has had two miscarriages since the birth of this child at two and three months respectively, the last one about five years ago. About that time, however, she began having severe pains in her muscles and joints, shifting in character, but focalizing in the feet, with some burning and swelling. The pains came on in February while she was living near Los Angeles, but disappeared in about two months, and she recovered completely. In October following she weighed from 165 to 175 lbs. About this time her menses ceased, and she began to have "queer" feelings in her arms, which seemed heavy and useless, with some burning. In December she began having shifting pains again, which continued for about two months; and during this time her child became ill and she nursed it night and day, with the result that she was in a state of nervous prostration. Meanwhile she had become much crippled with the pains which she called "rheumatism." There was no fever. On March 1 she began having peculiar feelings in her throat and abdomen, and her husband reports that two days later she became very much excited and disturbed mentally. The mental disturbance, with great excitement and at times confusion with definite delusions and hallucinations, persisted. But during the last few weeks she has lapsed into a state of mental dilapidation with apparently progressive dementia. Seven weeks ago she developed an extremely sore mouth and diarrhea, said to have followed a dose of calomel. The diarrhea and the condition of the mucous membrane grew worse rapidly, apthous sores appeared all over the mouth, the tongue was swollen and beefy, and at the same time there developed a great irritability of the bladder, inflammation and swelling about the vulva with a dull red appearance.

Two weeks after the onset of the gastrointestinal trouble the patient began developing a symmetrical pigmentation over the knuckles of both hands and along the radial sides of the index fingers. This pigmentation was red like sunburn, the skin was much thickened and between the thumb and forefinger on both hands some blebs appeared. The same pigmentation occurred over the nose, chin and cheeks, and the skin became thick and encrusted. There was vomiting frequently. And during these weeks of gastrointestinal trouble the patient had great pain in both legs below the knees, requiring opium as a sedative. She complained constantly of great burning in the feet. The muscles were exquisitely sensitive in the legs and generally over the body and she walked with a great deal of muscular ataxia. The pupils were small and reacted very slowly to light. The knee jerk, at the time we observed her, was practically abolished; and although the other reflexes were present, they were much diminished. The pulse was rapid (110-116), but there was no elevation of temperature. This condition continued for about a week after our first observation, when the patient died seeming to have gone to pieces from exhaustion.

It will be observed that in this case there was no neuropathic taint, although the nervous system was in a very low state of resistance from physical and mental strain at the time of the onset of the disease. In the following case, however, it is apparent that the soil for developing a psychosis was well prepared, both by autothonous and environmental conditions:

CASE II.—Miss S., unmarried, 26 years old, a teacher by occupation, was first seen June 6, 1914. Gives a history of neurotic temperament as a child. She was the sixth of eleven children, but has always been the favored one of the family, and has always been considered a little "queer." About nine years ago she had a nervous breakdown and passed through a period of depression. She passed through this, however, and was in fairly good health for several years afterward, but with an occasional return of mild depression and nervousness. In the spring of 1912 she suffered from a great deal of pain up and down her spine and in the great muscles of the back, and at about the same time she had an attack of diarrhea extending over ten days or two weeks without any apparent cause. Shortly after this she placed herself under the care of a chiropractic, but became very much worse. In the early part of her summer vacation she was exposed to considerable nervous irritation and excitement incident to a family reunion at her home, which left her in a very nervous state, the pain in the back having persisted. At this time the trouble seemed to be confined to the severe pains in her back muscles, with a developing tendency to insomnia. By Christmas time there was so much general prostration and depression that she was obliged to give up her work, and a little later went for a trip in the mountains. While on this trip she noticed a beginning pigmentation on her hands, face and forehead.

A few weeks later, under the influence of the sun and exposure at the beach, she became very much pigmented; at the same time her insomnia and depression became very pronounced, and she threatened suicide. Shortly after this she was placed in a sanatorium. Here she developed shortly a severe cystitis, with frequent, painful urination, and pus in the urine; and about this time the pain which had been confined to her back for a year became general, with considerable muscular tenderness in the arms, thighs, and calves. Two weeks after the appearance of the bladder symptoms the patient developed an irritation of the lower lip, with marked swollen erythema, becoming dry, cracked, and crusted. A week later an extensive ulceration of the mouth began with sores under the tongue and throughout the buccal cavity, a thick, beefy tongue, and swollen, spongy gums. At this time there was a

great tenderness all through the abdomen, frequent and persistent diarrhea, loose watery evacuations, with occasionally a little blood-stained mucus. There was extensive inflammation of the genital mucous membranes which were red, swollen, and beefy looking. The face presented a marked pigmentation extending over the forehead, following the hair line down into the temples, over the malar eminences and over the nose. The skin had the appearance of a very severe sunburn, but was dry and thickened, with a tendency to the formation of a crust over the nose. And a similar condition appeared progressively over the knuckles of both hands and along the radial sides of the index fingers. These areas were sensitive to touch, and the patient complained that they felt as though seared. She complained also of general sensory disturbance throughout the chest, and a burning sensation in the back and arms. At this time there was a slight elevation of temperature, from half a degree to a degree and a half, and her mental condition was that of a profound depression with a great deal of restlessness.

Case III.—Mrs. C., 64 years old, who passed through the menopause at fifty without incident, and up to about six months previous to our first examination in July, 1918, had been in excellent health. She gave a history of some minor intestinal disturbance, but her chief complaint was a bearing down feeling which led her to believe there was a uterine prolapse. About this time there developed a dry erythema on the wrists, back of the hands, and to a certain extent on the forehead. This eruption on the hands extended from the wrists to the first joints of the fingers, was a dull red color, and there was a tendency to form small blebs. The eruption was symmetrical on both hands, did not involved the palms or the palmar surfaces of the fingers. The dermatitis on the forehead was less pronounced and gave little discomfort. At this time the patient complained of sleeplessness; and the members of her family noticed that she wandered about her room a great deal at night, talking to herself. She seemed perfectly rational in the daytime. Two weeks later it was found that the dermatitis on the hands had extended practically to the elbows, so that now the backs of the hands, fingers and arms were a mass of scabs, blebs and sores. At this time there was very marked intestinal disturbance and a watery diarrhea. The tongue was now red and swollen, but the eruption on the face had almost entirely disappeared. The mental symptoms had become very pronounced. The patient had the delusion that some one was waiting for her outside, or that some one was trying to get into the windows, and had hallucinations of hearing. At this time there was no particular weakness manifested, or at least the condition which had formerly kept her in bed, that is, the feeling of prolapse of the uterus, was entirely forgotten and she no longer complained about this.

From this time on until the date of her death, four months later, there was a gradual but steady exacerbation in all her symptoms. The eruption on the hand increased in its intensity so that the backs of the hands were a mass of sores and the skin on the fingers and arms were constantly peeling and scaling off in large flakes. The tongue continued to be red, swollen, and the entire buccal cavity was congested. The diarrhea persisted and continued to be watery in character. The mental symptoms developed so that her delusions were quite as pronounced in the daytime as at night. She became very restless, so as to require constant attention day and night, and lost all appreciation of her surroundings. During all this time she was on a forced diet and was given large doses of arsenic, iron, and various tonics, without checking the progress of the disease.

There was nothing in the history of this patient to suggest a reason for the development of pellagra. She was an intelligent woman, in comfortable circumstances, had shown no peculiarities about her diet, and was in good physical condition. There was no neuropathic taint in the family, and, curiously enough, corn and cornmeal products were rather distasteful to the patient.

It will be recalled that the absence of pepsin and free hydrochloric acid in the stomach was thought at one time to be almost pathognomonic of pellagra. In our series of cases we have not found this deficiency in gastric secretions a constant factor in the disease, our observations being closely similar to those of Givens[1] who says in summary: "No definite relation can be found between the absence of pepsin and free hydrochloric acid, and sex, age, duration of pellagra, and clinical symptoms . . . Although the tendency is for acid and pepsin to disappear hand in hand, such is not always the case; . . . It is believed that pepsin and free acid are present more often than has been expected."

It is a common observation of physicians in the pellagra zone that there are many cases of "masked pellagra" which frequently escape detection. Thus Dr. J. F. Yarbrough,[2] of Columbia, Alabama, points out that in a small percentage of cases dermatitis does not appear at all except occasionally a short time before death. He concludes that: "The presence of burning sensations of the lower limbs and feet, general digestive derangement, tenderness over the abdominal area, general weakness without seeming cause, redness of the throat extending to a well-defined line just above the pillars of the tonsils, a red, sleek, fissured, or putty-colored tongue, and the peculiar nervous symptoms described above, I believe warrant us in making a positive diagnosis of pellagra, although there is no sign of dermatitis."

We have not come in contact with this type of cases, and do not find any record of such. But, of course, masked cases would easily escape detection here, or elsewhere, in regions where pellagra is a comparatively rare disease.

Dr. Yarbrough has also observed a peculiar type of dreaming in these cases, which he regards as characteristic of pellagra. "Dreaming is a most annoying symptom in many instances," he says. "On waking, the patients relate some of the most horrible experiences imaginable through which they have passed; some of them endeavor to hide these symptoms, and deny for a long time that they have ever had any such dreams."

In several of our cases, particularly in the beginning of the disease, we have observed a peculiar type of nocturnal delusions, or perhaps hallucinations and delusions, in which the patient wanders about the room somewhat dazed and confused, but does not express any particular type of dreams. In these cases the mental condition had progressed to a state of actual mental aberration, whereas none of Dr. Yarbrough's cases showed a definite psychosis. It is possible, therefore, that the dreams described by Dr. Yarbrough are simply forerunners of or substitutes for the nocturnal delusions and hallucinations which appear in later stages of the disease.

In the Southern States a very high percentage of pellagrins complain of burning sensation in the lower limbs, and have the characteristic dermatitis on the dorsal surface of the feet. In cases observed by us neither of these symptoms has been constant. Only about 40 per cent. of our cases complained of burning sensations in the lower limbs at any time, and less than 20 per cent. had dermatitis on the feet. But all of our patients were adults, and none of them had had their feet and ankles exposed to

the sun for any length of time, as would be the case with barefoot children.

However, the most striking feature of our series of cases was the economic condition of the patients as contrasted with most of the cases reported from the South. All of our patients were in comfortable circumstances, enabling them to have diets that were satisfactory in quantity, quality, and variety. Indeed, there is not a single instance in which food deficiency could be determined by ordinary observation, as was often possible in the series of cases reported by Goldberger and his associates.

In this connection, a series of cases recently reported by Dr. J. Ross Snyder[3] of Birmingham, Ala., offers very striking evidence that whatever the true etiology of the disease may be, diet is apparently an important factor. Dr. Snyder's series consisted of seven pellagrins in one family (the entire household) and three in another, both families living in the same neighborhood. The sanitary conditions of the family in which all of the five children and the father and mother were affected suggested at once that the disease was due to an infection, corroborating the conclusion reached by the Thompson-McFadden Pellagra Commission. The family was living in dirt and filth, their chief articles of diet being poorly baked biscuit, potatoes, and molasses. Dr. Snyder says that the only suggestions of protein food were the flies which swarmed everywhere about the place, food included.

The other family, in which three children were infected, presented a striking contrast to this first family in everything save one particular. In this second family the children were kept scrupulously clean, the house and premises were well cared for, the sanitary arrangements were excellent, and the earning capacity of the father was such that the household was able to have considerably more than the bare necessities of life. The one particular in which these cleanly pellagrous children resembled their dirty neighbors was the fact that they did not eat meat, milk, or eggs. Not from necessity, but from choice they were living upon a diet corresponding very closely in caloric values with that of their ill-kempt neighbors, minus the flies and dirt. Their food preferences were for cereals, fruit, bread and syrup, butter cakes, and green vegetables cooked with fat meat, and it was necessary to bribe them to partake of meat, milk and eggs.

It is significant, however, that when these articles were added to their diet the symptoms of pellagra disappeared; and it was a series of similar experiences that forced the conclusion upon Dr. Goldberger[4] and his associates that "the pellagra-producing dietary fault may be corrected and the disease prevented by including in the diet an adequate supply of animal protein foods (particularly milk, including butter and lean meat)."

Of course, the fact that certain diets make a person immune to pellagra, or cure the disease, does not prove that pellagra is a food-deficiency condition, or disprove that it is an infection. It is possible that the disease is caused by some organism which finds suitable soil for growth in the systems of the persons whose resistance is lowered by a diet wanting certain food elements. But in any event it is evident that diet is an important factor in many cases of pellagra, perhaps in all cases; and although the evidence of this was not developed in our series of cases, it is possible that such food deficiencies did exist, and might have been discovered had we been given an opportunity to make careful observations prior to the development of the advanced symptoms.

BROCKMAN BUILDING.

HAYFEVER AND ASTHMA.

BY WILLIAM SCHEPPEGRELL, A.M., M.D.,

NEW ORLEANS.

PRESIDENT, AMERICAN HAYFEVER PREVENTION ASSOCIATION, EX-PRESIDENT AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY, CHIEF, HAYFEVER CLINIC, CHARITY HOSPITAL.

AN analysis of 707 cases of hayfever in the Hayfever Clinic of the Charity Hospital and in private practice, has shown that 37 per cent of the cases developed asthma at some period of the disease. In many of these cases the attacks were light, and at long intervals; in others, the asthmatic attacks were so severe and frequent that it formed the predominant feature of the disease.

In the immunizing treatment of hayfever in the Clinic, the cases which were complicated with asthma gave practically the same results as those with the uncomplicated form.[1] As a result of this, an increasing number of patients began to apply for treatment when apparently suffering from asthma only.

These patients were given our diagnostic test for hayfever, in order to determine which of the cases were due to hayfever. When this proved negative the cases were referred to other clinics. The results of these tests indicated that there are many cases of hayfever in which the nasal symptoms are so mild as to be almost unobserved or even entirely absent, and in which asthma is the predominant feature.

Diagnostic Test.—The diagnostic test in hayfever consists of an injection of 5 units of pollen extracts, of the strength of 100 units to the cubic centimeter, into (not under) the skin, and the reaction noted in 20 minutes. The pollen extracts used are those of the atmospheric-pollen to which the patient is exposed, as determined by the pollenometric plates.[2]

In most cases, the pollens are limited to three forms, as we have shown that all the common hayfever pollens may, from a biological standpoint, be divided into four classes,[3] and there are rarely more than three of these present in any locality. The classes are as follows:

Classification of Hayfever Pollens.—1. *Ambrosiaceæ*, the principal representative of which is the common ragweed, *Ambrosia elatior*, the chief cause

of fall hayfever in the United States. It is found practically in all sections east of the one-hundredth meridian, except in some sections where it is replaced by the giant ragweed, *Ambrosia trifida*.

This group also includes the so-called "false ragweed," *Gaertneria*, and the marsh elders, *Ivas*, whose pollens are as active as those of the ragweed, but which have a much more restricted geographical distribution.

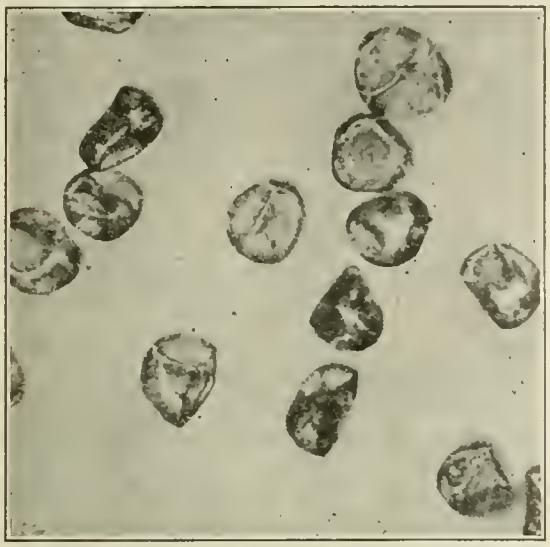

Fig. 1.—Pollen of June Grass, *Poa annua*, representing the Gramineæ class. Pollens collapsed from exposure, characteristic of this group. Magnified 500 diameters.

2. *Gramineæ*, which includes all the grasses, including the cultivated forms, and which are common in practically all sections of the United States. The grasses are the chief cause of spring-summer hayfever in all sections.

3. *Chenopodiaceæ*, which includes the amaranths,

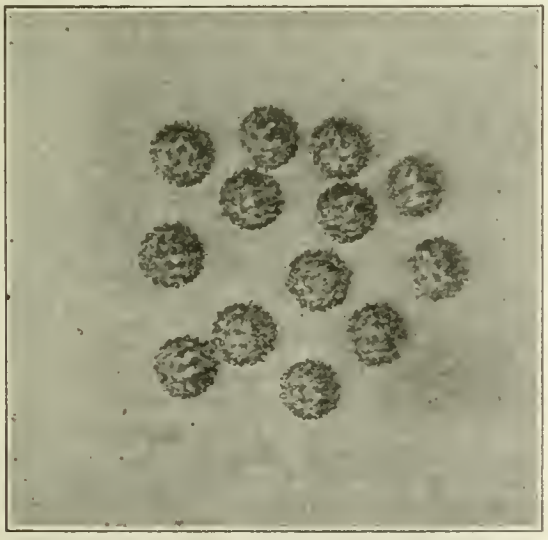

Fig. 2.—Pollen of Common Ragweed, *Ambrosia clatior*, the type of the Ambrosiaceæ group. From an atmospheric-pollen plate. Magnified 500 diameters.

chenopods, docks, and Russian thistle, some varieties of which are found in most of the States.

4. *Artemisias*, or wormwood group. There are many varieties of this group, but they form an important factor only in the Pacific and Rocky Mountain States. The wormwood sage, *Artemisia frigida*, is of interest as it grows at elevations as high as 6,000 feet, and is frequently an unsuspected cause of hayfever in such localities.

Recording Diagnostic Tests.—When the diagnostic test has been made, the result is noted and recorded on the percentage basis, as we have found this more practicable than attempting to describe the reaction by "positive," "marked," "severe," etc. A severe reaction, in which the wheal is 2 c.m. in diameter and a corresponding areola of redness, is marked 100 per cent, and lesser reactions in proportion.

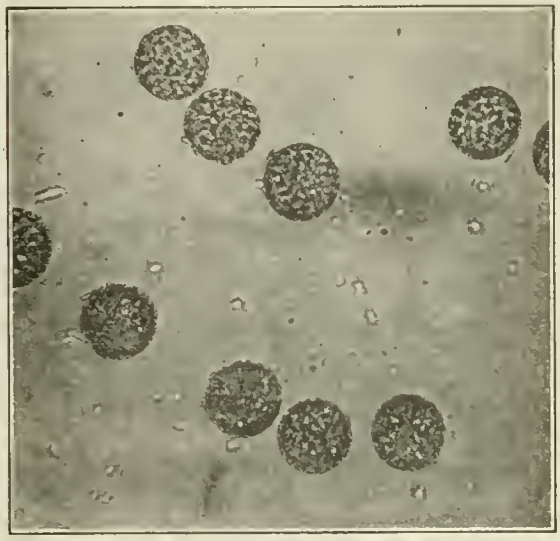

Fig. 3.—Pollen of chenopod or Goose-Foot, *Chenopodium anthelminticum*, representing the chenopodiaceæ group. Magnified 500 diameters.

Cause of Reaction.—The dependence of asthmatic attacks on digestive disturbances is well recognized, and the regulation of the diet is a common form of treatment. The effects of pollen in the nostrils of anaphylactic subjects gives rise to what may be called a "nasal indigestion." The protein of the pollens, which are absorbed and subjected to the

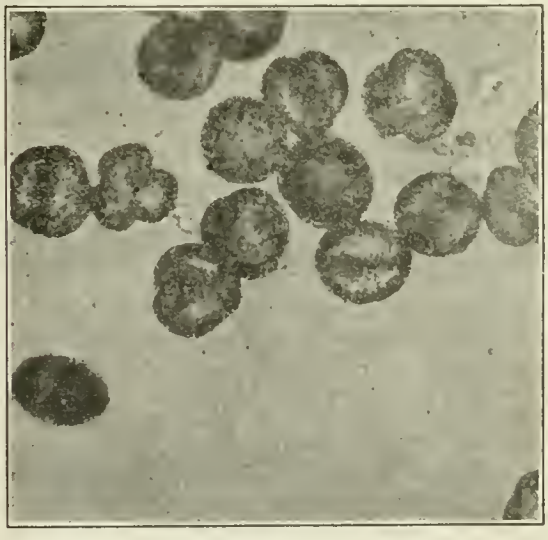

Fig. 4.—Pollen of Wormwood, *Artemesia heterophylla*, representing the Artemesia group. Magnified 500 diameters.

proteolytic action of the cells, are not digested and assimilated as in the case of normal subjects, and the products of this imperfect digestion give rise to the hayfever or asthmatic reactions.

Synchronicity of Asthma and Hayfever Attacks.—An important feature in the history of asthmatic cases is the question of synchronicity with the prevalence of hayfever. This is not absolutely reliable, however, as the atmospheric-pollens vary considerably in different localities.[4] In New Orleans, for instance, we have a certain percentage of perennial hayfever, with or without asthma. This was at first difficult to explain until the atmospheric plates showed, in some localities, the presence of the pollen of the false wormwood, *Parthenium hysterophorus*, which blooms during every month of the year.

In northern Texas, also, there is a form of hayfever in January, which the atmospheric-pollen plates showed to be due to the pollen of the mountain cedar, *Sabina sabinoides*, which was formerly not associated with hayfever.

It must also be remembered that asthmatic attacks, even though originally due to pollen protein, may afterwards arise from other causes, and they may therefore appear outside of the usual hayfever seasons.

Treatment.—The treatment of hayfever asthma, during acute exacerbations, does not differ from that in other forms of asthma.[5] The diet and hygienic regulations are also similar. The immunizing treatment, however, in both the prophylactic and curative forms, is conducted on the same principles as that of hayfever.

After the diagnostic test has determined the form and degree of the sensitization, 20 units of the indicated pollen extract is injected under the skin of the arm, the site having first been sterilized with iodine. The injections are repeated at intervals of two or three days, the units being increased by 10 to 15 units until the maximum dose is reached, which, in most adults, is 150 to 200 units. This number should be used as long as indicated. The doses for children should be in the usual proportion for their ages.

Marked reactions indicate that the doses should be more gradually increased, or even reduced. These reactions consist of slight hayfever attacks, and occasionally of a more or less general skin eruption resembling miliaria which may persist for several days.

When the symptoms indicate catarrhal complications, a vaccine, preferably autogenous, should be substituted for one to four doses of the pollen extracts.

Results of Treatment.—The results of this form of asthma due to hayfever has given us approximately the same as from the uncomplicated form, *viz.* 45 per cent. seasonal cures, 43 per cent. improvements, and 12 per cent. without benefit.

When the immunizing treatment has been successful, as indicated by a negative skin reaction, and the asthma persists, this shows that there are other excitants for the paroxysms, and a careful examination should therefore be made to determine the cause.

AUDUBON BUILDING.

PSEUDO-MÉNIÈRE'S DISEASE.

(ANGIOSPASM OF THE INTERNAL AUDITORY ARTERY.)

BY A. LEPRINCE, M.D.

NICE, FRANCE,

LARYNGOLOGIST TO THE HÔPITAL ST. ROCH.

ON December 21, 1918, I was called by my confrère, Dr. Drapier, surgeon of the St. Roch Hospital, to see one of his patients, M. L., 66 years of age, who had been suffering for several days from attacks of vertigo resembling Ménière's disease. The first attack occurred December 17 and lasted from two to three hours. On December 20 a very severe attack occurred which was accompanied by vomiting for several hours.

When I saw the patient for the first time I remarked that Ménière's syndrome could not be present in this case and I saw that we were in the presence of some vascular disease the nature of which it was impossible to make out at the first visit, especially as the patient was now in a condition of semistupor. After a brief examination we applied leeches to the mastoid process and the result of this treatment was nil. The attack lasted for forty-eight hours, and the patient gradually got better up to the 30th of December, when a third attack occurred accompanied by three or four periods of vomiting. The vertigo lasted for forty-four hours in spite of the measures instituted to reduce the congestion of the middle ear and the administration of a remedy designed to lower the arterial tension which was then + 18 by the Pachon apparatus.

Before continuing the recital of this case I would recall briefly the characteristics of the Ménière type of vertigo and note the difference existing between the classical syndrome and the symptoms of M. L. which we are now considering. In Ménière's disease the attack is sudden. In the midst of perfect health the patient is taken with deafness, vertigo, tinnitus aurium, nausea, and vomiting. The attack is often so violent that the patient falls unconscious. Sometimes the subject does not lose consciousness entirely but can neither stand nor walk. In all cases the attack begins with vertigo; then when the patient recovers from this, hearing is found to be greatly weakened or entirely lost either on one side or both. The vertigo may last for several days and is increased in the dark or when the patient shuts his eyes. As regards the auditory function, Ménière's disease is of grave prognosis, for the deafness does not diminish.

The phenomena in the case of M. L. were as follows: At first the attacks followed each other with marked regularity, occurring about every ten days

—Dec. 20, Dec. 30, Jan. 10, Jan. 20, Jan. 30, Feb. 10, Feb. 21, etc. The attack always began by the progressive diminution of hearing in the left ear. The watch normally heard at 10 cm. could be heard only at contact and later by bone conduction alone. It seemed to the patient as though hearing disappeared gradually and the sensation of fulness increased more and more and at its maximum a sensation of compression was felt, and then vertigo appeared and lasted for a few hours up to forty or fifty hours according to the severity of the attack. From the very beginning of the attack a marked redness of the ear was noticed which did not persist but returned after the vertigo had subsided. At the same time a sort of whistling sound and a peculiar feeling of malaise informed the patient that the attack was at an end.

Now, what is the nature of the vertigo itself? Sometimes M. L. seemed to turn with external objects, at first from left to right and then from right upon the diminution of the sharpness of hearing with a sensation as of a pledget of cotton left in the ear. At night he noted a slowing of the heart beats, often rather painful, and during a trip to Paris he consulted Dr. Potain, who attributed the trouble to dyspepsia. This was cured by appropriate treatment but the condition of the ear was not modified and the patient was in an extremely nervous condition. He returned to Paris in May, 1890, at which time he began to suffer from a peculiar vertiginous condition which he compared to the sensation of being on board ship. In spite of Scotch douches, lavage of the nose, and a season at Plombière the general condition of the patient grew worse and the sensation of fulness and deafness in the left ear increased. Sometimes pressure of the hand on the ear caused an apparent displacement of objects which returned to their proper position as soon as the pressure ceased. One night the patient was awakened by extreme malaise and great nausea and

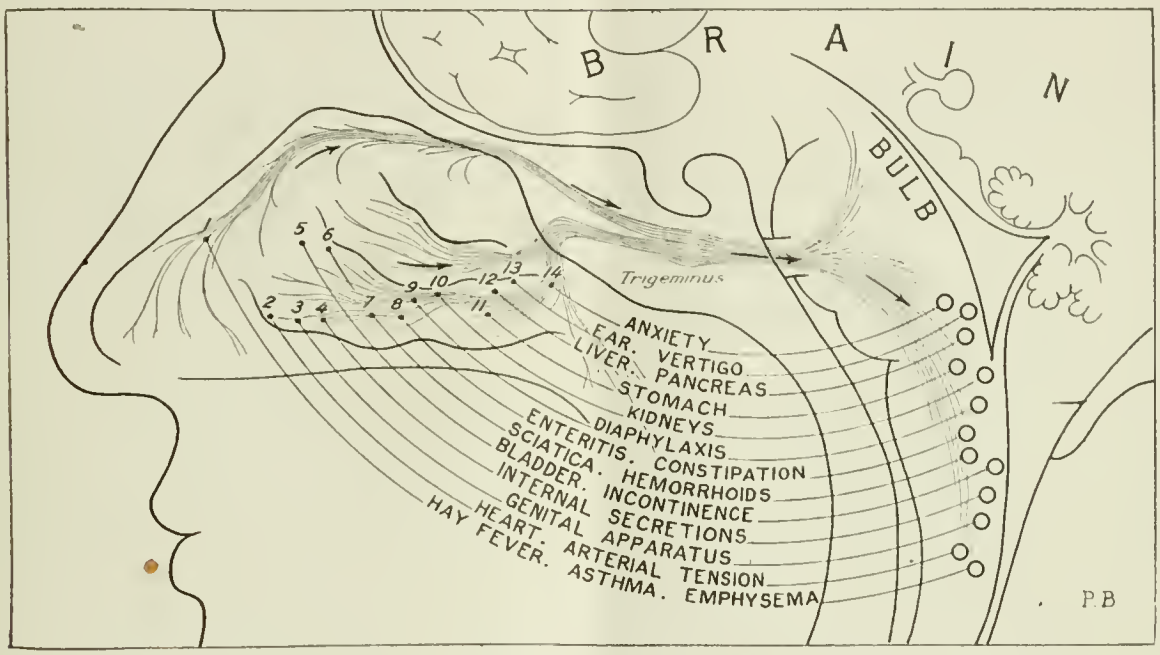

Diagram showing points in the turbinal corresponding to various centers in the oblongata.

to left or vice versa. Sometimes he seemed to be a little outside of the center of rotation. During the attack of vertigo the patient could not bear the light and he kept his eyes closed, for whenever he opened them the vertigo was increased. The slightest noise made it worse, even the distant ticking of a clock, for as soon as the vertigo appeared the hearing returned.

If now one compares these two descriptions, it will be evident that in the case which we are reporting the symptoms appear in the inverse order from those of Ménière's disease, and that even the character of the vertigo is of inverse type to that of Ménière's disease. Now, in studying the history of this patient and going back for several years I learned he had suffered from muscular rheumatism following which he had contractures of the internal and external muscles of the thighs which were cured by hydrotherapy. M. L. had besides suffered in 1890 from some ear trouble while spending the winter of 1889 and 1890 at Nice. And he remarked vertigo during which objects seemed to pass before his eyes with great rapidity. This was followed by obstinate vomiting, cold sweats, and a syncopal condition. Quinine was prescribed. After the attacks, as above noted, the patient's hearing always improved. This was contrary to what takes place in Ménière's disease, in which the hearing does not improve.

Some days after this attack M. L. went to Paris to consult Dr. Gellé who made a diagnosis of left labyrinthine migraine caused by mild tubal catarrh. He advised treatment by means of inflation with the Politzer bag, and vaporization of boiled milk with the addition of cherry laurel water, but this brought no relief and the attacks returned every three or four weeks, always announced two or three days in advance by deafness, an increased sensation of fulness in the ear, and general malaise. The duration of the attack was five or six hours and it was accompanied by vomiting and syncopal attacks terminating in a crisis which brought relief to the con-

gestion of the ear together with return of hearing. The normal condition of health was established at the end of about 48 hours. In comparing the attack of 1890 with those of 1918 and 1919, we noted that the same symptoms occurred in the same order—deafness, tinnitus, vomiting, vertigo, return of hearing, and general malaise. The diagnosis of Dr. Gellé, "labyrinthine migraine," seems to us correct if we use the term migraine in the same sense as we employ it in speaking of ophthalmic migraine. As to the etiology "determined by the mild tubal catarrh," the treatment followed without success would indicate that it was erroneous.

During the present attack M. L. has the sensation as though the tube was closed, although the Valsalva experiment and the Politzer tube showed there was nothing abnormal with the Eustachian tube itself. Several aurists who were consulted were unable to solve the mystery of the disease. Politzer denied the existence of labyrinthine disease and made the diagnosis of compression of the internal meatus by swelling of the tube and mucous membrane of the middle ear.

In 1902 he had two attacks for which Dr. Lermoyez prescribed quinine in small doses, which leads us to believe that the trouble was diagnosed as Ménière's disease. In 1909 the patient suffered from several attacks of false angina pectoris, which were regarded at the time as true angina. Up to the month of November, 1918, there was no return of the vascular trouble, when at that time, following an attack of the grip, he had some disquieting cardiac manifestations. Dr. Drapier, who was now consulted, suspected the presence of endocarditis, and auscultation revealed quite a marked murmur.

We now come to the first attack of the present disease, which occurred on December 17, as I have noted above. This history of attacks in 1890, 1902, and especially the attack of false angina pectoris in 1909, then the more recent cardiac disturbance in November, 1918, led us to believe that we had to do here with an affection analogous to ophthalmic migraine, which is a spasm of the calcarine artery, and with a false angina which is a spasm of the coronary arteries. The attacks on January 9 of vertigo lasting fifty hours, and the vertiginous condition for a few days following the attack, and that of January, lasting three days, confirmed us in the belief that we had to deal here with a spasm of the internal auditory artery. This artery is a branch of the basilar and accompanies the auditory nerve to the bottom of the internal meatus, where it divides into the vestibular and cochlear arteries. The vestibular branches follow the same course as the nerves and split up into capillaries in the saccule, utricle, and semicircular canals. The branches to the cochlea pass into the modiolus and pass through the spiral canal into the membranes and the periosteum of the cochlea, which latter is very vascular, especially at the level of the spiral ligament. An arteriole independent of the preceding enters the aqueduct of the vestibule and divides into several branches in the vestibular cavity. Another arteriole follows the duct of the cochlea and terminates in the round window and the periosteum of the cochlea. Finally, there is still another arteriole passing into the petrous portion and ramifying in the semicircular canals. The veins follow the same course as the corresponding arterial branches before entering into the petrous sinus. One can readily understand from this anatomical description that when a spasm of the internal auditory artery takes place there would at first be a slight anesthesia of the ear, marked in this case by deafness (first phase of the attack). When the spasm relaxes suddenly the blood returning into the labyrinth causes tinnitus (cochlear reaction, second phase); then vertigo occurs (vestibular reaction, third phase); the circulation being now restored again in the ear its sensibility returns (return of hearing, fourth phase).

Now how can we relieve this spasm? After the attack of January 20 I induced M. L. to submit to nasal cauterization, which was made on January 26 at the head of the inferior turbinal, and a little beyond so as to act upon the general circulation and the general tonicity (cardiovascular and genital zones, Nos. 2 and 3 of the illustration). The following day, January 27, I made a second cauterization at the same place. The arterial tension was 16. The attack occurred, nevertheless, on January 31, lasting forty-eight hours, and the following days were very wretched, with malaise and great weakness. A consultation was held with Dr. Hirschberg, the neurologist, on the 27th. He advised leeches and the application of an ice bag. These measures did not prevent the occurrence of the seventh attack on February 11—an attack of prolonged vertigo lasting three days with photophobia. Because negative results followed most of the medication I persuaded the patient to submit to nasal cauterization on the vertigo point lying at the posterior and upper part of the lower turbinal (No. 13 of the diagram). This cauterization was proposed on the 30th of January but the patient did not consent. Because of the failure of treatment and the aggravation of symptoms it was finally done after the appearance of the eighth attack, on February 21. On this day hearing was diminished from the early morning. Redness of the pavilion of the ear occurred and the appetite was lost. At 3.30 o'clock I cauterized the vertigo point (No. 13) in the left nostril. That evening the sensation of fulness and deafness increased. The night was rather comfortable and the patient slept. On February 22, at 6.30 in the morning, the deafness attained its maximum. It was generally at this time in other attacks that vertigo occurred but on this occasion it was absent. The patient awoke from a deep sleep at ten minutes past seven, awaking quietly though there was a little photophobia. The appetite returned and he was able to take soup four times that day. The morale was excellent. At 7 o'clock in the evening the sensation of fulness diminished, and the hearing began to return at 8.30. A very considerable clearing up of the ear was noticed and the ticking of a watch was again heard. The attack could then be regarded as terminated and followed its usual course, but there was no vestibular reaction; notwithstanding that the following night was disturbed and the patient suffered from general malaise, there was no vertigo.

On the morning of the 23d the watch could be heard better. The sensation of fulness of the ear had almost disappeared and the attack passed away without malaise or vertigo. The appetite returned and the patient's morale was excellent. This was

at 10 A. M. It seemed then that we had been successful and that the patient was definitely cured, but at 11 o'clock there was some malaise, attributed bp the patient to a whistling which ordinarily accompanied decompression and clearing up of the ear. At 2 o'clock the malaise increased and continued until evening but the patient's morale remained good. At 7 o'clock in the evening there was an improvement in the general condition but the patient was extremely nervous and passed a restless night. He feared a return of the attack. The deafness returned on the 25th and I found the patient in an anxious condition with irregular heart and intensely nervous, all these symptoms being due to lack of sleep for some days and to fear of a new attack, more serious than the preceding. I then made some slight cauterizations in the zones of the liver; constipation, circulation and anxiety. (Nos. 2, 8, 12, 14.) There was almost immediate reaction, marked by nausea, intermittent congestion, and loss of consciousness of very brief duration occurring on February 26 and 27. There was a slight gyratory vertigo on the first of March and after this hearing gradually returned and there was a progressive amelioration. On March 2, when the ninth attack should have occurred, we noted a definite cure. From that date M. L.'s general condition was changed, the appetite returned, the morale was excellent, and within a few days he resumed his occupation and took an interest in his affairs, correcting manuscript, to the great astonishment of his family, and he seemed in better condition than he had been for some years past.

I will not add any comments to this already too long report. Perhaps it would have been better not to have made the cauterization of the 25th of February, so near the end of the attack. I yielded, however, to the desire of the patient and of his family, but the stimulation of the bulb caused by the multiple cauterizations fatigued the patient already greatly weakened by two months of illness. In a similar case I would advise the cauterization of only one zone at a time and the repetition of the cauterization some days later if found necessary. However, in spite of the nervous crisis provoked by the cauterization a complete cure was obtained. The secretion of bile was reestablished, the stools became of normal appearance and constipation disappeared, and at the final consultation there was no cardiac murmur to be heard. The patient's condition of anxiety had given away to a feeling of confidence in himself so that, as we said above, within a few days he resumed his usual occupation which he had given up during more than three months of illness.*

In order that the reader may gain a definite idea of the points touched by the galvanocautery I will refer to the diagram which is copied from the one presented to the Société de Biologie by Dr. Bonnier in March, 1916. It will be seen that most of these centers are rather near to each other and that their distribution on the anterior turbinal corresponds to the bulbar centers in such a way that one of the lower centers (that of the heart) corresponds to a point near the anterior extremity of the turbinal. In order to act upon the vertigo center in the upper part of the medulla the cauterization must be at the posterior end of the turbinal. The difficulty in carrying out the method is evidently not in touching but in touching the exact spot.

33 Boulevard Gambetta.

*I saw Mr. L. on July 15, 1919, and learned that he had had no attack since February 25. His condition is very good, and the patient considers himself cured.

Medicolegal Notes.

Compensation for Medical Services to Wife.—In an action for medical and surgical services performed for the defendant's wife, the defense was that six months prior to the time the services were rendered the wife had left the defendant without cause and was living separate from him at the time of her death. There was no evidence that the defendant had a house prepared and ready for his wife at any other place than that where she was staying at and before the plaintiff's services were sought and engaged. She was then staying at a rooming house. The defendant frequently visited her, and stayed at the rooming house many nights, and during a part of the time remained there every night. It was testified that immediately after the defendant's wife died he requested that her earrings be taken off. The evidence also showed that the defendant visited the hospital where his wife was receiving medical and surgical treatment. He held himself out to the plaintiff, and to others, as the husband of the patient. The plaintiff testified that the defendant, after the death of his wife, in a conversation relating to the plaintiff's compensation, said "he would pay the bill." It was held that these and other circumstances justified the trial court in finding for the plaintiff.—Reahard v. Miller, Colorado Supreme Court, 179 Pac. 157.

Warranties in Life Insurance.—In an action on a life policy the Indiana Appellate Court says that it appears to be a settled rule in the law of life insurance that answers to questions propounded by the insurer, in an application for insurance, will not be construed as warranties unless they are clearly shown by the form of the contract to have been so intended by both parties. And when this is done they must then be strictly and literally true, or the contract of insurance becomes voidable. Where both the application and the policy bore the statement of the assured that, "He expressly warrants his answers to be literally true," his failure to give the names of all the physicians by whom he had been treated within seven years before the time of the making of his application, as thereby required, by omitting the name of one of them, constituted a breach of warranty, and where the company after his death elected to annul the contract, it was not liable thereon.—Modern Woodmen v. Hall (Ind.), 121 N. E. 835.

Exclusion from Schools for Nonvaccination.—In a proceeding to test the right to exclude a schoolboy from a public school in North Dakota on the ground that he had not been vaccinated, it appeared that there is no statute in the State of North Dakota making vaccination a condition precedent to the right to attend the public schools, so that the court did not express an opinion upon the constitutionality of such a statute. It was held that section 400 of the North Dakota Compiled Laws of 1913, making it the duty of the board of health to make and enforce all needful rules and regulations for the prevention and cure of contagious and infectious diseases, does not authorize the board of health to issue an order denying to children the right to attend the public school except upon condition of being vaccinated where it appears that there is no prevailing epidemic of smallpox and no immediate danger from this disease is reasonably to be anticipated. Sections 1346 and 426, defining the duties of school officers with reference to the supervision of the health of school children and their exclusion from schools when infected with infectious or contagious diseases, was held not to authorize the exclusion for nonvaccination, in the absence of a showing of danger due to the existence of smallpox in the community, or that such danger is reasonably imminent.—Rhea v. Board of Education, North Dakota Supreme Court, 171 N. W. 103.

Medical and Surgical Lessons of the War.

THE LABORATORY SERVICE IN THE AMERICAN EXPEDITIONARY FORCES.

By RALPH G. STILLMAN, M.D.,

NEW YORK.

FORMERLY MAJOR, M. C., U. S. A., OFFICER IN CHARGE OF LABORATORY, BASE HOSPITAL NO. 9, A. E. F.

No adequate conception of the laboratory service of the American Army in France can be obtained without a preliminary realization of the difficulties under which that service was instituted and the rapidity with which it was developed. At the outset there were great deficiencies in material and somewhat lesser deficiencies in the size of the personnel. The first step in advance was the organization of the Division of Laboratories and Infectious Diseases, in the fall of 1917, with Col. J. F. Siler as director, and with headquarters at Dijon. It would scarcely have been possible to select a better man for this position, for Colonel Siler had many years of productive laboratory life to his credit, and under his expert and courteous leadership the Division of Laboratories developed rapidly into the best organized and most efficient of the sections or sub-departments into which the Medical Department of the A. E. F. was divided. The choice of headquarters was also a happy one. Dijon was situated in the advance section of the Service of Supply, not far from Chaumont, the general headquarters. It is an old and very delightful city, the seat of an ancient university which boasts of numerous scientific accomplishments. The city marked the farthest advance of the Prussians in 1871, and the Croix de Guerre was added to its arms in memory of the heroic resistance presented on that occasion.

The first base hospitals sent to France were among those which had been organized under the auspices of the Red Cross before the United States entered the war. They left this country carrying with them a fairly adequate equipment, furnished in part by the Red Cross and in part by the parent institution at which they had been organized. At that time the supply tables of the Manual for the Medical Department contained only the simplest laboratory equipment, such as is essential for the ordinary routine examination of the blood and urine. In consequence the laboratories of these hospitals carried a varied equipment, which was large or small, depending upon whether a large or small amount of money had been donated for the purpose. Later organizations, camp hospitals, field hospitals, etc., had practically no laboratory equipment, and had to be outfitted after they reached France. Ocean transport was so congested that such materials came from the United States only very slowly. They could be purchased abroad only in small quantities, and after searching many markets. But gradually these difficulties were overcome. The Council of National Defense issued a revised paragraph 846 of the Manual for the Medical Department (laboratory apparatus) which contained everything that could be needed for a well equipped laboratory, and every effort was made to have on hand in France a complete list of these articles. Requisition for laboratory supplies had to pass through headquarters at Dijon, and was subjected to careful inspection so that the supplies on hand could be distributed fairly, and one laboratory could not enlarge its equipment at the expense of the service as a whole. Each laboratory was required to submit a complete inventory of its property so that the director might know how the supplies were distributed. Standard forms of equipment were drawn up and the mobile laboratories, especially, were fitted out with a set of chests, themselves well adapted for use as laboratory furniture, and containing everything necessary for carrying on a large amount of work.

One of the fundamental difficulties, as was to have been expected, was the question of fuel. Gas was often unobtainable, and in those places where its manufacture continued was usually supplied for only a few hours during the day. The supply of alcohol was often very small, and occasionally disappeared entirely. It was not easy to obtain bunsen burners adapted for use with gasolene. Kerosene was generally available, and the Primus, or some similar burner, made a useful stove. Electricity was generally to be had, since the French had established central lighting plants early in the war in order to lessen the use of oil and candles. The scarcity of coal at times threatened the continuity of the supply of electric current, but so far as I am aware it was never broken. These were inconveniences, but were not crippling, and it was possible to get along with rigid economy. This matter of economy, by the way, was not the least of the valuable lessons learned by the American officers in France. The fact that money was of but little value in comparison with materials that could be replaced only with great difficulty was a new one, and often not easily assimilated, but was thoroughly appreciated before our forces had been long in France.

Several things are worthy of comment in regard to the electrical equipment. The current furnished in France is generally a 110 or 220-volt alternating current of 50 cycles, and either two or three phases. The alternating current in this country is generally of 60 cycles, and the difference may be of importance in the selection of motors, especially the larger ones. It was of especial importance in *x*-ray plants, where the speed of the motor is of greater importance. The smaller American centrifuges are well adapted for use with any current, but it is often difficult to get a larger one that will run on the current. The lamp sockets used in France are of the Continental type, with spring contacts and a bayonet catch, not the screw-in type to which we are accustomed. This made it difficult to replace burned-out lamps used as resistance in some of our apparatus, though it was possible to devise a makeshift that would work. Also it was very difficult to get carbon filament lamps for resistance purposes, as their manufacture was discontinued because they used so much current.

Deficiencies in personnel were quantitative rather than qualitative. The need for combatant troops made it impossbile to have an adequate number of enlisted men in the medical department. It was possible to make up this lack in part by the use of convalescent patients for the lighter work, and the rest was accomplished by working the permanent personnel at a higher pressure. Soon after

the organization of the Division of Laboratories a questionnaire was submitted to all medical officers who had had laboratory training, and a careful inspection was made of incoming casual officers to determine their suitability for this work. Officers that were available and whose qualifications seemed satisfactory were ordered to Dijon for a course of training at the Central Medical Department Laboratory. At the completion of the course they were assigned to duty according to their capacities as observed during their stay in the Central Laboratory. Before the armistice was signed there was available a well-trained staff of laboratory officers, large enough to meet the demand at the time. These men were shifted from place to place, depending upon the demands of the moment, so that in an evacuation hospital during a "show" there were often six or even eight men engaged in nothing but wound bacteriology. Statistical clerks, who would have been so valuable in collecting data and tabulating results, were lamentably rare. There should be one or more in every laboratory. It was a delight to see to what an extent the enlisted personnel could be trained in the performance of laboratory procedures. They soon were able to do routine uranalyses satisfactorily, and many clinicians were heard to remark that their blood counts were generally more reliable than those done by the average junior interne in a civil hospital. They made culture media, did Wassermanns, made cultures and Carrel counts, examined sputum, and took blood cultures in a reliable and conscientious manner. They absorbed this knowledge as a sponge does water, and at all times exhibited an enthusiasm that was inspiring.

There were many types of laboratories established in the A. E. F. which functioned pretty much as one would expect from their names. Army, Corps, Divisional, Base Section, Evacuation Hospital, Base Hospital, Camp Hospital and Hospital Center, and Mobile Laboratories were the titles under which they passed. The Central Medical Department Laboratory was located at Dijon with the Headquarters. Here were given courses in wound bacteriology, the typhoid-colon group, the pneumococcus-streptococcus group, the control of water supplies, and the preparation of the "gum-salt solution" which was used for a time in the treatment of shock. These courses were short, not over two weeks in duration, and to them officers were ordered as they could be spared from their regular work. At Dijon there were also working chemists and physiologists, and a department of food and nutrition was established which did excellent work in the supervision of the feeding of the troops and in the standardization of mess management. A certain amount of research was carried on here as time and material offered. It was at this laboratory that museum specimens were collected and prepared for shipment to the United States.

The work done in the laboratories was classified under six headings, as follows: Clinical Pathology, Anatomical Pathology, Bacteriology, Serology, Chemistry, and Operative Procedures. While the character of the work differed in the various types of laboratories at different times they were all prepared to handle practically all kinds of work, with the possible exception of the Wassermann reaction, which was done in but a limited number of places.

Clinical Pathology.—The ordinary examinations of the blood, urine, feces, sputum, gastric contents, spinal fluid, and venereal specimens did not differ materially from those ordinarily made in civil hospitals, except perhaps in amount. An attempt was made to get away from that pernicious practice, so generally followed in civil hositals, of making certain examinations as a "routine" on every patient admitted, regardless of his disease. This was necessary because of the smallness of the laboratory personnel in comparison with the size of the hospital, and was greatly facilitated by the clinicians, who ordered examinations only for some good reason. This procedure enabled a limited personnel to do careful and conscientious work, and gave much more satisfactory results than would otherwise have been possible. Included under the heading of Clinical Pathology are the so-called "Carrel counts," the count of the number of bacteria in films made from wound secretions. These were done in very large numbers, and it was felt that they yielded results which justified the time spent upon them. Thin films were made as evenly as possible upon glass slides, either from swabs or from wound secretion brought to the laboratory in a capillary pipette. These were stained according to Gram's method, when possible. In times of stress it was necessary to shorten the staining time, and resort was had to the use of a single dye, such as gentian violet or Loeffler's methylene blue. A red stain was found to be too trying on the eyes when a man had to spend several hours a day looking at these slides. The number of bacteria seen in ten or twenty fields of the oil immersion lens were counted and the average number per field reported. While it is admitted that this method lacks much in scientific accuracy, it gave surprisingly constant results. The significance of the Carrel count will be discussed with the bacteriology of wounds. Examination for the *Treponema pallidum* was done with the dark field apparatus when this could be obtained. Stained preparations were much less satisfactory. Colloidal gold reactions were not universally done because the reagents could not always be obtained.

Anatomical Pathology.—This consisted principally in the performance of autopsies and the examination of material obtained from them. The number of autopsies performed varied with the activity of the service. In some hospitals it was possible to autopsy every fatal case, but in others, where the mortality was high, it was necessary to make the post-mortem examination only in cases of particular interest. Two points were emphasized. The autopsies should be performed as soon after death as possible, and they should be as complete as possible. They revealed a very large number of interesting and instructive conditions, and, since they were well attended, as a rule, by the medical officers, they had a distinct educational value. In some places the pathological and radiographic departments worked together. *X*-ray plates were made of the chest after death and the findings correlated with the condition revealed at the autopsy. In this way a definite advance was made in the interpretation of roentgenographic findings in chest conditions, especially in regard to bronchopneumonia, in

which the *x*-ray picture not infrequently closely resembles that obtained in miliary tuberculosis. Operation specimens were comparatively few in number. When interesting specimens, or those which would be valuable for teaching purposes, were met, they were forwarded to a central point and there prepared either for museum specimens or to be sent to the United States to be used in the instruction of medical officers here. The study of these specimens yielded much information as to the action of modern projectiles, in addition to the aid given in formulating a plan of treatment. Naturally the material obtained varied with the location of the laboratory. Deaths from wound and from gas poisoning occurred practically only in the advanced areas, while in the hospitals in the rear the deaths were chiefly from medical conditions. Formalin was scarce early in the war, but was easier to obtain later. The salts necessary for the making of Kaiserling preparations were very difficult to obtain, so that this method could be used only to a limited extent. The photographic section was not fully developed at the time the armistice was signed. Chemicals were scarce and print paper very difficult to find. But this would soon have been a very valuable means for the preservation of unusual and instructive specimens.

Bacteriology.—Bacteriological examinations, except those of wound tissues and exudates, were quite similar to those carried out in peace times, although on occasions the volume of the work was tremendous. All things considered, the bacteriological work formed the principal part of the laboratories' labors. Blood cultures were made in the infectious diseases, and were generally a part of the autopsy routine. Urine cultures were not frequently asked for. Cultural examination of the stools was at times an important part of the work. Several epidemics of dysentery, apparently not of the ordinary bacillary type, occurred in the A. E. F., especially in the summer of 1918, and a large number of stools were examined for the dysentery bacilli. Examination for typhoid bacilli was less frequently required. Endo's medium was used by choice, though MacConkey's bile salt agar, used by the British, and Krumwiede's brilliant green methods, both had ardent supporters.

The identification and typing of pneumococci obtained from the sputum was a frequent procedure during the time when pneumonia was prevalent. White mice were exceedingly difficult to find, so that Avery's method was almost universally adopted. It was the experience of the A. E. F. that the hemolytic streptococcus was a rather less frequent cause of pneumonia than it was reported to be in the United States. The pneumococcus found was comparatively infrequently a type I variety.

Throat cultures for the diagnosis of diphtheria were frequently made. Two negative cultures from the throat, taken at an interval of at least 48 hours, were required before patients convalescent from diphtheria could be discharged. No new or efficacious method was found for ridding the throat of diphtheria bacilli after an attack of the disease, and the protracted stay of some of the patients in the hospital was annoying both to the patient and to the staff. Similarly, two negative cultures from the nasopharynx were required for the discharge of meningitis patients. It was early brought to the attention of the medical officers that meningococcic meningitis was frequently a bacteriemia in its early stages, and cultures from both the blood and spinal fluid were generally made. Serum was given both intravenously and intraspinally in many cases. Examination of large bodies of men for carriers of the diphtheria bacillus was not done. The disease was endemic in many of the French towns, and cases in the A. E. F. could often be traced to this source. Examination for carriers of the meningococcus was not made as extensively as was advised by the British during the first years of the war. The practice in the A. E. F. was to isolate and examine only the immediate contacts after the appearance of a sporadic case, and to go through the whole organization only after the appearance of secondary cases. This procedure was justified by results, for there was relatively little meningitis in the A. E. F.

When indicated, and possible, it was attempted to make fairly complete cultural examinations at autopsies. A blood culture was often a routine, and the percentage of them showing pneumococci or streptococci was surprisingly large, although it perhaps represented an agonal infection. Material was generally planted upon blood-agar plates, unless there was reason to suspect the presence of anerobes, in which case anerobic cultures were made. A very satisfactory medium for anerobic work was devised at the Central Medical Department Laboratory, and called liver-peptone water. Ordinary peptone water, containing one per cent. peptone and one-half per cent. salt, was made, and adjusted to a reaction of minus two. This was filtered and tubed, and to each tube was added a cube—measuring about one centimeter on a side—of fresh liver, either rabbit, beef, or human. The tubes were then autoclaved. These tubes were boiled, and cooled shortly before using in order to drive out dissolved air. After inoculation a loopful of calcium sulphide was added and the surface of the medium covered with liquid petrolatum. All of the group of bacilli of gas gangrene grow luxuriously in this medium.

At one time numbers of cultures were made from the throats of medical officers, nurses, and orderlies in an attempt to discover whether any great percentage of them were carriers of the hemolytic streptococcus. The percentage found was quite high, especially among the nurses, but it was not possible to show that this condition had any influence upon the development of streptococcus infections in the wards, whether in the respiratory tract or in wounds.

The bacteriological examination of drinking water was of prime importance, and was carried on to the exclusion of the chemical examination. Much of this work was carried on by the water supply laboratories, small mobile laboratories especially fitted up for this purpose, whose personnel came jointly from the Engineering, Medical, and Sanitary Corps. It was soon found that practically all of the natural water supplies in France are quite heavily contaminated, so that treatment was always essential. The treatment consisted generally in the application of chlorine, either as chloride of lime in the well-known Lister bags, or in large tanks, or as liquefied

chlorine gas added by means of an automatic chlorinator. The latter apparatus was installed only in permanent posts having a central water supply and of sufficient size to warrant its installation. Filtration was occasionally resorted to. Frequent cultural studies were necessary to check the action of the treatment used. Lactose bile was used for the ordinary presumptive tests for colon bacilli and plain agar for the numerical estimations.

Wound bacteriology was one of the most important laboratory functions after our troops entered the front line. This subject had been developed only since the outbreak of the war, and had to do largely with certain pathogenic anerobes which have been grouped together under the name of bacilli of gas gangrene. Through the courtesy of the French and British bacteriologists, our laboratories were able to collect the available information on the subject, and a course in wound bacteriology was given at the Central Medical Department Laboratory in order to enable our bacteriologists to become familiar with the technique and the characteristics of the organisms. The matter was one of the greatest importance, for the satisfactory treatment of war wounds is possible only when carried on with the close cooperation of the surgeon and the bacteriologist. The method of control was roughly according to the following scheme: As soon as possible the wounded man was subjected to the operation of débridement; that is, all devitalized tissue was excised and the wound thus rendered practically sterile. If the operation had been done within eight to twelve hours after the wound was received, the time depending upon the kind of tissue involved, it was possible to close the wound immediately, and it generally healed well. This was called primary suture, and was not done unless the patient was to remain in the hospital at which he was operated upon for a sufficient time to allow the outcome to manifest itself. If infection had already developed in the tissues, or if the patient was to be sent back to another hospital, the wound, after operation, was packed and dressed. At any time after this, within about six days—that is, before the development of hard granulation tissue or the epithelization of the wound surface—it was possible to suture it together, provided the culture showed the absence of the hemolytic streptococcus or appreciable numbers of the anaerobes. This procedure was known as delayed primary suture. If, because of infection or other cause, delayed primary suture was impossible, it became necessary to perform the operation known as secondary suture. This operation could be successful only with favorable bacteriologic conditions. It consisted in the removal of granulation tissue and a freshening of the wound surfaces, followed by suture. In preparation for this operation the wound was treated according to the Carrel method. Cultures were made from the wound to determine the nature of the infection, and Carrel counts done every other day to discover any change in the number of bacteria present. When the wound appeared to be clean and the bacterial count became low another culture was taken to determine whether a secondary suture could be done with safety. The presence of the hemolytic streptococcus or of pathogenic anaerobes was a contraindication to suture. The staphylococcus was relatively innocuous, while the colon bacillus occupied a position somewhat between these two extremes. Members of the proteus group were able to cause trouble by their proteolytic powers. Often it was not necessary to wait until the wound exudate was absolutely sterile before secondary suture could be performed. Staphylococci could be present to the number of three or four per field without preventing suture, and even streptococci have not caused failure in numbers as high as one per field. A number of nonpathogenic organisms can be ignored entirely. The results of this bacteriologic control of treatment were exceedingly satisfactory. When possible, it was desirable for the bacteriologist to accompany the surgeon on his rounds and himself to take samples of wound exudate at the time of the dressing. Such specimens were obtained in capillary pipettes, and the material could be inoculated directly into liver-peptone water and on blood-agar plates, and in addition could be examined in the hanging drop, a method that often gave valuable results very quickly. When the amount of work was so great that the bacteriologist could not leave the laboratory the material was collected on swabs similar to those used in making throat cultures. Films were made on slides for bacterial counts. At first, blood-agar plates were inoculated by rubbing these swabs over the surface of the plate. But it was soon discovered that this method gave negative results in a large number of cases when the streptococcus was present. Later the swabs were placed in broth and incubated for about four hours and the fluid then inoculated on the plates. This method yielded a much higher percentage of positive results. It was possible to return preliminary reports in from twelve to twenty-four hours, and this was sufficient for the surgeon's purpose.

Complete forms were devised for the recording of the results of this work. One form, in duplicate, carried a complete bacteriological report of the case, with a résumé of the clinical history, and accompanied the patient from place to place. When the case was completed one copy was sent to Dijon. A monthly summary of all the work in wound bacteriology was forwarded also to headquarters. This report included the kinds of organisms found and the results of suture operations. This mass of material was being analyzed, and had the war lasted a longer time the information derived from these reports would have been available to all of the allied surgeons.

Serology.—The Wassermann reaction was the principal serologic procedure. In the beginning it was ordered that all Wassermann reactions for record must be performed at Army Laboratory No. 1, but the mass of the work was so great and the delays in the mails so troublesome, that the scheme was soon abandoned. A limited number of laboratories were designated as places where the Wassermann would be performed, and various hospitals sent their specimens to the nearest place. As the army grew, the number of these laboratories increased until they were quite numerous. Since Wassermanns on any given patient might be done in a number of places, and as the technique differs widely with different workers, it was thought wise to prescribe a standard technique and identical reagents. The method decided upon was that of

the ordinary Wassermann technique with an anti-sheep hemolytic system, warm bath fixation, a quarter-unit dose, and the taking advantage of the natural amboceptor when present. Warm fixation was necessary because of the difficulty of getting ice in most places. Antigen and amboceptor were produced and standardized at the Central Medical Department Laboratory and furnished to the laboratories as needed. The antigen was a half cholesterinized alcoholic extract of beef heart, which worked very well, but showed a tendency to develop anti-complementary properties. The results of this standardization were very satisfactory. Guinea pigs were rather easy to obtain in the summer of 1917, as they are raised by the French peasant for food. Later the demand became so great that the supply was inadequate, but the Red Cross scoured the country for animals, and was able to collect a fairly large number. The practice of aspirating the blood from the heart enabled one animal to furnish complement for a very large number of reactions, provided he was allowed a sufficient rest between bleedings.

The grouping of bloods for transfusion purposes was an important duty. A commission of surgeons and laboratory men adopted a standard technique both for the method of grouping and for the giving of transfusions. Type sera for diagnosis were furnished from the Central Medical Department Laboratory, and with them fresh supplies could be obtained from the personnel of the hospital. The classification used was the Moss system, in which Groups II and IV are the more common ones and Group IV is the universal donor. The method used was to place a drop of Group II and Group III serum at either end of a clean slide. A small drop of the person's blood is mixed with each drop of serum, and the agglutination which takes place observed with the naked eye. If agglutination occurs in the Group II serum only, the blood is of Group III; if in the Group III serum only, it is in Group II; if agglutinated by both sera, it belongs to Group I; while if it is not affected by either it is in Group IV. The naked-eye observation can be checked by the microscope, but is astonishingly reliable, and the whole procedure takes but a minute or two. It was suggested at one time that all of the men in the army be grouped and their group number stamped on their identification tags. However, it was never possible to do this. In many of the hospitals the members of the organization were grouped so that it was always possible to find a suitable donor in case of an emergency. The citrate method and a simple apparatus were used for transfusion. Although the possibility of preserving human red cells over comparatively long periods of time had been demonstrated it was never put into practice. Fresh blood was considered preferable, and could almost always be obtained.

Agglutination tests, both for the diagnosis of disease and for the identification of bacteria, were frequently done. Serum for this purpose was furnished from Dijon, the supply in some instances being obtained from the Pasteur Institute in Paris. The use of the Dreyer technique for the quantitative estimation of agglutinins for the typhoid and paratyphoid bacilli was, unfortunately, not officially adopted in the A. E. F. This method utilizes a standardized emulsion of the bacterium in question and reports the result in terms of certain arbitrarily selected units. It is of great advantage when dealing with patients who have received prophylactic doses of typhoid-paratyphoid vaccine. Typing of meningococcus strains was done with Pasteur sera, and the type therapeutic serum for these strains was obtained from the same source.

Chemistry.—Chemical examinations were seldom done. Few laboratories were equipped with the necessary apparatus and reagents. Some little blood chemistry was done with the microcolorimeter, and estimations of the carbon dioxide capacity was done in connection with the investigation of the question of surgical shock. Chemical examination of the drinking water was not made, for it was felt that the bacteriologic study gave all of the information required. For a time there was some demand for the examination of water for poison, but it gave such scanty results that it was soon dropped.

Operative Procedures.—The number of these varied in different laboratories. Treatments with salvarsan, therapeutic sera, and bacterial vaccines were generally carried on by the clinical personnel. Schick tests were generally done by the laboratory staff, but not in large numbers. There was comparatively little call for animal inoculations other than of mice. At times the laboratory personnel assisted in the performance of transfusions, but this was not a general practice.

Miscellaneous.—The supply of therapeutic sera was handled through the laboratory. Antitetanic, antidiphtheritic, antimeningococcic, and antipneumococcic sera could be obtained in sufficient quantities, usually manufactured in the United States, but at times supplied by the Pasteur Institute in Paris. A serum was also developed against the gas gangrene bacilli, and was issued during the last two or three months of the war. The results of its use have not yet been made public, so that its value is not known. The laboratory officer was also called upon to make sanitary surveys and to pass upon water supply systems and methods of sewage disposal. It was interesting to note that where septic tanks were in use the material was at times pumped out of them and spread upon the fields for fertilizer. It was impossible to find evidence of any bad effects from this practice. When attached to a hospital the laboratory officer often found himself in the position of an unofficial and impartial arbiter when questions arose between the clinical divisions. No mention has been made of the research work which was carried on in the American Expeditionary Forces. Some few of the investigations, those into the cause and treatment of shock, the study of the bacilli of gas gangrene, and the development of a therapeutic serum, are more or less well known, but the great bulk of this work can become public only as it appears in the medical press. It was often carried on amid great difficulties and was interrupted at times by the urgent demands made by emergencies, but when all is known it will reach a large amount.

Reports of various kinds were furnished at the instance of the Division of Laboratories. Mention has been made of those required in wound bacteriology. A copy of each autopsy protocol was sent to Dijon, where it was reviewed and more informa-

tion asked for if deficiencies were found. Each month a summary of all the work done in the laboratory for that period was sent in, so that it was possible to judge whether any individual laboratory was doing either too little or unnecessary work. Other special reports were asked for, such as on the prevalence of streptococcus carriers and the bacteriology of the pneumonias which occurred in France.

This paper must necessarily give but an imperfect idea of the accomplishments of a section of the Medical Department that was divided into very small units, which naturally were more or less isolated from each other. An effort was made, wherever possible, to standardize methods and equipment, and in that way to increase the efficiency of the force as a whole and to make individual reports of comparative value. This advance in laboratory work has been urged for many years by a few, and it is hoped that the ground gained will not be lost now that the army is disbanded. The Division of Laboratories also functioned as a training school, and there are many expert laboratory workers and technicians now in this country who acquired most of their expertness and experience in their army service. The personnel as a whole was characterized by the same enthusiasm and loyalty to their particular section as was so generally exhibited by other branches of the service. Its members felt that they belonged to the best organized and most efficient arm of the Medical Department, and each did his level best to keep it so.

OBSERVATIONS ON EMPYEMA THORACIS IN CAMP HOSPITAL NO. 26, 1918-1919.

By SAMUEL S. ROSENFELD, M.D.

1st Lieutenant, Medical Corps, U. S. Army.

The following are observations on thirty-five consecutive cases of empyema thoracis treated on the surgical service of Camp Hospital No. 26, 1st Repl. Depot. The cases were all secondary, in most instances this was the sequence: influenza, bronchopneumonia, and finally empyema. Cultures in nearly all of our cases revealed the pneumococcus. Our youngest patient was thirteen years of age and our oldest was thirty-one. There was one female civilian in the series.

The symptoms and signs conformed in the majority of cases to the usual text-book description of this disease, but in an appreciable number of patients we found marked bronchial breathing and excellent transmission of voice sounds over areas in which we had proven the existence of a large purulent exudate.

In making the diagnosis every case is carefully interrogated and examined. No examination is considered complete without an *x*-ray and fluoroscopic examination and the complete laboratory investigation of the fluid obtained by aspiration.

The technique as now practised is the one recommended by the Empyema Commission of the United States Army. No patient is operated on until the following conditions are fulfilled: (1) The presence of frank pus. (2) The *x*-ray or fluoroscopic proof of the presence of adhesions walling off the abscess cavity or cavities (as shown by Major Graham and Capt. Bell of the Empyema Commission a walled off cavity protects the mediastinum and the opposite lung from the malicious influences of an open pneumothorax). (3) Absence of pneumonia. Until all these conditions are fulfilled, aspiration is practised.

In operating local anesthesia is employed—novocaine 1 per cent. A simple intercostal incision, the site of which has previously been determined by fluoroscopic examination, has been found amply sufficient and very satisfactory. In making the incision great care is taken not to go beyond the boundaries of the cavity, so as not to infect the general pleural cavity, which nature has walled off for us. The ribs are spread, adhesions inside the cavity are carefully broken up, and Carrel tubes are inserted into the cavity. Five tubes are usually inserted at the time of operation, but after the third dressing four are usually replaced and have always been found sufficiently able to take care of the entire cavity. Dakin's solution accurately prepared and titrated is instilled every two hours during the night and day. The aim is to keep the cavity about one-half full of the antiseptic solution during the entire twenty-four hours.

The wounds are dressed daily and at this time the cavity is flushed with Dakin's solution. The flushing is accomplished by the introduction of a No. 22 French catheter into the cavity. After the flushing the tubes (Carrel) are replaced, each one receiving an equal amount of Dakin's solution at each two-hourly instillation, the amount depending on the size of the cavity, but never exceeding two hundred c.c. for the entire cavity. After several fluoroscopic examinations, we are satisfied that when the Carrel tubes are correctly placed in the cavity, every part of the cavity is reached by the solution at least every two hours. Bacterial smears are made from the surface of the wound and from the cavity every two days and a chart indicating the number of bacteria per field is kept. We have found a small Carrel tube placed on the surface of the wound and receiving ten c.c. of Dakin's solution every two hours very efficacious in sterilizing the surface wound.

In our experience the sinus leading from the surface wound to the empyema cavity is more rapidly sterilized when the perforations of a Carrel tube are so placed that they come in direct contact with the entire sinus tract, thereby allowing the sinus to be flushed with Dakin's solution every two hours.

The tubes are withdrawn as the bacterial count reaches the "sterile line", provided the discharge and the clinical aspect of the surface wound warrant it. Secondary closure has been unsatisfactory in the few cases in which it was attempted. Breathing exercises are given twice daily for fifteen minutes, and during the day the patients are encouraged to blow against resistance. We are certain that this part of the treatment is rational, for after studying patients for varying periods of time, aided by the fluoroscope, we have noted that the best lung expansion and the greatest amount of diaphragmatic excursion, accompanied by the greatest amount of obliteration of the former empyema cavity, occurred in those patients who were most particular and efficient in the matter of lung exercise.

The matter of feeding these patients is quite important. We have paid special attention to this matter, encouraging them to eat as much as possible. The food given was of high caloric value, and

at the same time a special effort was made to please each individual patient's palate. Practically all of them gained in weight, and some of them as much as thirty pounds.

We have also noted that patients while receiving the Dakin's solution run a mild febrile course, which, however, does not interfere with their appetite, well being, or improvement.

We have had two cases of double empyema, both occurring in negroes. One of them in addition had a pneumococcus abscess beneath the thyrohyoid muscle. They were both cured. One of them was treated by aspiration only. This is the only case in which operation was not performed. We had one patient, a French civilian, who for quite a while did not consent to operation. Numerous aspirations were performed, but the cavity continually refilled. Operation finally gave an excellent result, sterility being complete in twelve days.

We had two cases complicated by pulmonary tuberculosis. The empyema in both of these patients was easily controlled, notwithstanding the fact that one of them had two separate cavities. In both of these cases the wounds were entirely closed before the patients were discharged from the hospital. In one of them the tuberculous lung condition rapidly progressed and in the other it did not seem to activate the process. There were two cases complicated by bronchial fistula. One of these closed spontaneously and we succeeded in closing the other one by injections of bismuth-iodoform paste into the tract. In this patient an autogenous vaccine was made from the discharge on the tract wall, and the discharge disappeared after the third injection, but the tract remained open. Two injections of bismuth-iodoform paste gave us a complete closure. He was discharged from the hospital on March 7, 1919, and was last heard from in May, 1919. The wound had remained closed. The other bronchial fistula occurred in a patient, a lieutenant in the Dental Corps. He had a massive double pneumonia with two separate cavities on his left side, one of them connecting with a bronchus. He was treated by aspiration until the disappearance of pneumonia and then both cavities were opened under local anesthesia. He bore Dakin's solution without any trouble in the cavity not connected with the bronchus, but at first had violent coughing spells when the solution was introduced into the cavity connected with the bronchus. However, by gauging the amount of solution which he could bear without coughing, 5 to 10 c.c. every two hours, we were able to obtain sterilization and the fistula closed spontaneously after removal of the tubes.

We had experience with the autogenous vaccine in five cases. In four of them the organism recovered by the laboratory was the *Staphylococcus albus*. In the other it was the pneumococcus. The vaccines were used in patients with chronic discharging sinuses. After the discharge diminished bismuth-iodoform paste was injected. There was complete closure in two cases and a great diminution in discharge and in the size of the cavity in the other three.

There were two deaths in the series and, as a study of the clinical record and autopsy reports show, these deaths occurred very early in the series, before the adoption of the procedure recommended by the Empyema Commission. One of them was not walled off, the exudate still being seropurulent, and the other still had an active pneumonia. Since the adoption of the Empyema Commission's procedure there have been no deaths.

Conclusions.—Empyema is a surgical disease and should be treated as such. Aspiration is only occasionally curative, but it is of utmost utility pending the walling-off process, disappearance of pneumonia, etc. We can corroborate the statement of the Empyema Commission with regard to the most favorable time of operation, namely, in the absence of pneumonia, in the presence of a walled-off cavity which is usually expressed by the character of the exudate, frank pus, and which can also be determined by fluoroscopy and the *x*-ray. The latter means of determination should never be omitted. Local anesthesia suffices for all acute operations and the intercostal incision, in the great majority of instances, will prove sufficient. The Carrel-Dakin method gives excellent results. A short Carrel tube placed on the surface is very effective in sterilizing the wound. To prevent reinfection and chronicity it is very important to obtain a sterile sinus. Breathing exercises are very important, as is the feeding. Vaccine and bismuth-iodoform paste proved valuable in our small number of chronic cases. We had one cure in a case of bronchial fistula by the careful use of bismuth-iodoform paste (Morison's bipp).

Fifteen Hundred Cases of Chancre.—Levy-Bing and Gerbay saw during three years of war 1,500 cases of syphilitic chancre in soldiers, two-thirds of which were contracted in the interior zone. A still greater proportion were contracted from women who were "picked up" and comparatively few in houses of prostitution. Extragenital infection was not common—less than 3 per cent. In every case of chancre a laboratory diagnosis was made.—*La Presse Médicale.*

Epithelioma Cured by Intercurrent Erysipelas.—Jersild does not state that the erysipelas cured the cancer, but that the latter "recovered spontaneously after an attack of erysipelas." The male patient was but 24 years of age and presented himself with an ulcer on the point of the nose, taken at first for syphilitic. The lesion had extended to the septum narium and was of a verrucous appearance. There was submental adenopathy. The Wassermann was positive, but there were no evidences of syphilis. Biopsy showed epithelial pearls. At this juncture the patient contracted erysipelas of the nose and chin with bullae and edema of the eyelids. It migrated toward the ears and beyond the chin. The course of the infection was brief but the ulcer rapidly healed and with it the adenopathy. The strongly positive Wassermann might have been due to the cancerous process as many similar cases are on record.—*Hospitalstidende.*

The Influenza Pandemic in Japan.—This country was visited by influenza for the first time in the present pandemic during the winter of 1918-9. Over 20,000,000 people were attacked and the mortality up to Feb. 1 alone was 240,000. The native scientists believe that the cause is a filtrable virus present in the sputa and blood which attacks the mucosæ of the respiratory tract.—*Le Progrès Médical.*

The Eugenic Society of Sao Paulo.—The annual meeting of this society shows that much interest is taken in the problems of eugenics in this progressive Brazilian city. Some of the leading medical men of the community are active in their cooperation. The society in question is affiliated with the Prosanitary Society of Brazil and the president of the latter is also honorary president of the Sao Paulo Society. The immediate object of the latter is to secure the reform of certain statutes which antagonize eugenic developments.—*Annaes Paulistas de Medicina e Cirurgia.*

TREATMENT OF THE STOKES-ADAMS SYNDROME

ALTHOUGH usually due to a lesion of the bundle of His, the fact should not be overlooked that the Stokes-Adams syndrome may have a nervous origin, so that some reference will be made to the treatment to be adopted when an abnormal excitation of the pneumogastrics is in play. Medication with atropine in fractional doses may exercise a favorable action because, as is known, it suspends temporarily the action of the filaments of the vagus. If the cause of the pneumogastric irritation—origin of the bradycardia—can be detected, such as tracheobronchial adenopathy syphilitic mediastinitis, or gastropathy, it should be treated by appropriate measures.

This being said we will refer to the Stokes-Adams syndrome resulting from lesions of the auriculoventricular band. In the first place, the lesion may be recent, still undergoing its evolution, so that its nature is the first thing to be sought for. At present we know that syphilis is the most important casual factor in provoking lesions of the bundle of His and when it can be detected in time a real amelioration can be obtained, sometimes even a cure, and a number of cases have been recorded where antisyphilitic treatment worked wonders. Those reported by Erlanger, Esmein, Rénon, Ramond and Lévy-Brühl are very suggestive. When it has not been possible to determine exactly the nature of the lesion it is prudent to essay a specific treatment as a test, and Boubermann (Thesis, Paris, 1911) relates an instance of Stokes-Adams syndrome in which mercurial treatment was successful although there was complete absence of any signs which could give rise to a suspicion of syphilis in the patient.

When the change in the bundle of His—origin of a ventricular bradycardia—arises during an acute endocarditis or myocarditis, the usual treatment of the causal process may help to produce a retrogression of the inflammatory focus in the auriculoventricular fibers. Against arteriosclerosis, which can involve the heart and may cause a lesion of the bundle of His, various well-known physical and medical measures are to be advised, but failure to obtain results is usual. When the bradycadia is paroxysmal and due to a commencing lesion of the bundle of His, Vaquez advises the use of atropine which will often result in causing a certain number of cardiac contractions to take place normally, and therefore to produce longer intervals between the attacks. A half a milligramme of atropine sulphate is given in the morning in solution and continued for four days and then interrupted for four days, and so on. When the lesion is definitely constituted the change in the fibers of the bundle of His is too marked and profound to be influenced by any curative therapeutics, so that all the physician can do is to avoid the causal factors of the nervous paroxysms so far as is in his power when they have a tendency to recur.

Every violent physical effort on the patient's part must be avoided and absolute rest in bed for some time must be enjoined. A quiet life, free from emotions, should be followed. The digestive functions are to be watched and the diet should be of a light kind; a milk diet may be occasionally prescribed with advantage. In order to lessen or cut short an attack of syncope at the onset, which is always liable to occur, inhalations of amyl nitrite are to be recommended, and some patients, feeling the approach of an attack, instinctively lower the head in order to cause congestion of the brain.

RECOGNITION OF THE ENTAMŒBA DYSENTERIÆ.

ANY one who has spent weary hours searching for amebas in stools and attempting to differentiate different types of cystic forms will be eternally grateful for dependable criteria which will enable one to recognize these organisms. These criteria are furnished from one of the U. S. Army Laboratories by Kofoid, Kornhauser, and Swezy (*Archives Int. Med.*, 1919, xxiv, 35). The fact that non-pathogenic amebas are frequently found in stools is not generally appreciated to the extent it deserves. These authors in examining stools from 1500 men found the *E. nana* in 28 per cent., the *E. coli* in 23 per cent., and the pathogenic *E. dysenteriæ* in but 9.3 per cent. of the cases. In acute amebic dysentery it is generally rather easy to recognize the large free pathogenic amebas. The small forms are to be distinguished with difficulty from the *E. nana*, though this is an easy matter in properly stained preparations. But in suspicious cases or in patients who have been treated there may be no free forms present, and it then becomes necessary to determine the diagnosis by the recognition of the encysted forms. The authors recommend the study of the direct smear with the Donaldson iodine-eosin stain and assert that differentiation can be made, chiefly based upon the structure of the nucleus, generally without difficulty, though indeterminate individuals may be found. The characteristics are as follows:

E. coli is distinguished by size, color, and granulations of the cytoplasm, as well as by the prevalent eight nucleate cysts.

E. nana is distinguished by the abundance of cysts, the large, clearly defined glycogen mass when present, the prevalence of ellipsoidal or ovoidal cysts, the abundance of highly refractive granules, the absence of the central granule and the clumping of the chromatin on the nuclear membrane in a single blob.

E. dysenteriæ cysts are less abundant and are distinguished by their glassy, refractive, irregularly vacuolated or almost homogeneous cytoplasm, with distinct nuclei with heavy rim and central granule, never exceeding four in number, with relatively abundant mononucleates, and glycogen, when present, diffusely distributed.

The authors also give a description of a number of structures which are apt to confuse the examiner, some of which can be named. Their observation should be most helpful to those who have to search stools for amœbæ.

ROVSING'S SIGN IN CHRONIC APPENDICITIS.

Among the provoked pains of chronic appendicitis a special place should be given to pain produced by the forcing back of gas in the cecum and appendix. To this phenomenon the name of Rovsing has become attached, because he apparently was the first to study it. But the paternity of this sign does not in reality belong to the distinguished surgeon of Copenhagen. He unquestionably was the first to advise to search for pain by progressively pushing back the gas in the descending colon from below upward, then continuing to slide the hand, still pressing deeply from left to right, along the transverse colon and finally sliding it from above downward into the flank and right iliac fossa toward the cecum. This procedure, which is difficult to carry out properly, is due to Rovsing, and to it his name rightly belongs, but three years before he published his method in 1907, Walther of Paris demonstrated that free and deep abdominal palpation over areas other than the right iliac fossa provoked a pain in the appendix by gas distention of the cecum.

In all doubtful cases of appendicitis it is well to look for this appendicular pain by distention of the cecum, which will generally give valuable data. With the right hand applied flat on the middle and left part of the abdomen, deep pressure is made, forcing the intestinal gas back toward the right segment of the colon. Then the left hand is progressively pushed into the area of the righ colonic angle whereby the cecum becomes distended. By this technique, pain in the appendix from cecal distention is more readily realized than by Rovsing's method.

Not only is this sign very accurate, but it possesses another great advantage. In nervous subjects, direct palpation of the right iliac fossa—a region spontaneously painful—is rendered more difficult on account of the patient's apprehension, who instinctively contracts the abdominal wall. On the contrary, palpation at a distance does not awaken this distrust, so that an exploration can be carried out which would otherwise be impossible.

Bastedo has employed colonic insufflation for the production of pain in the appendix, and had positive results in chronic inflammation of the organ. This writer states that in cases of right-sided inflammatory lesions of the uterine adnexa a pain of lesser intensity may be produced by this means which shoots toward the middle line of the abdomen. It is possible that a differential diagnosis between chronic appendicitis and right-sided lesions of the adnexa can thus be made, although too much reliance must not be placed on it.

Radiography of the Appendix.

Recent work done in radiology demonstrates that to-day the shadow of the cecum and that of the appendix, much more frequently than is generally suspected, are easy to obtain, and by these researches the study of the large intestine has met with the same success as that of other abdominal viscera. In almost all cases some useful clinical data will be obtained on the shape, seat, relationship, and mobility of the cecum, which, during the evolution of various morbid processes, may become seriously changed. When occasionally the shadow of the appendix is obtained it may indicate its direction, size, relationship to other abdominal viscera, its mobility and situation, thus explaining certain morbid disturbances of which it is the seat. By exactly localizing the site of the painful spots, radiography will permit the clinician to eliminate the many cases of pseudoappendicitis that are encountered, and facilitate the differential diagnosis between chronic appendicitis and enterocolitis. It will likewise explain the accidents or symptoms which occur after surgical operations on the cecum and appendix. It is probable that radiography will never be able to show the exact morbid condition of the appendix by which one could conclude as to the operative indications, but appendicular calculi and concretions can be revealed on the plates. Nevertheless, the results obtained in France by Desternes, Dupuy, and Frenelle lead us to hope that some advance in this direction may yet be accomplished. The data obtained by these workers have resulted in bringing a most useful contribution to the diagnosis of typhoappendicular affections, and it may very well be that further researches, methodically carried out, will place this diagnostic means far above its supposed possibilities and importance so far as the appendix is concerned.

Dementia Paralytica or Poisoning?

The practitioner is not often called upon to differentiate between two such dissimilar conditions, but Dr. Van Minden of Amsterdam was confronted with this necessity and called in consultation Dr. Van Leersum, one of the leading internists in Holland (*Nederlandsch Tijdschrift voor Geneeskunde*, May 3). The patient was found at midnight in bed. He had been attacked by convulsions. Cyanosis was absent. He was quite disoriented. Pupils rigid, reflexes very active. To quiet his restlessness he was given morphine, with ice to the head, after which he slept. As typical nocturnal epilepsy could be excluded the provisional diagnosis of dementia

paralytica, or rather of a convulsive seizure in a subject of paresis, was made. Next morning the eyes, speech, and handwriting were studied. The patient was now oriented and was able to deny vigorously that he had ever contracted syphilis. Two days later the patient visited the physician, who found his eyes and speech normal. He admitted that on the evening preceding the attack he had attended a social gathering and had drank a little beer at the coffee house where the meetings were usually held. He noted at the time a strange taste which prevented his finishing his glass. The rest of the beer ordered was drunk by a comrade. Both began to feel queer and left the premises in haste. The patient lost consciousness, and on reaching home appeared strange to his wife. Professor Van Leersum excluded the idea of an acute intoxication, despite the fact that the other man was taken ill. Data as to the history of the latter fail, and no information is given as to the nature of the poison.

Adhesive Perigastritis in Gastric Ulcer.

Adhesive perigastritis resulting from ulcer of the stomach is made manifest by a group of symptoms which, although variable, nevertheless allow the diagnosis of these adhesions. Spontaneous pain is the principal symptom of adhesive perigastritis. Usually seated in the epigastric region, it commences by paroxysms of pain, the frequency of which progressively increases, and after a certain lapse of time—which may be very long—the pain becomes continued. It presents recrudescences after meals, likewise under the influence of certain movements or positions assumed by the patient. It is calmed by vomiting. Pain provoked by palpation of the epigastrium is very rarely wanting. It is either diffuse or localized, and in the latter circumstance it acquires a very considerable clinical value when its site corresponds with that of the spontaneous pains. The results obtained by palpation permit one to distinguish two varieties of adhesive perigastritis, namely, simple perigastritis and perigastritis with tumor. Radioscopy will complete the clinical diagnosis, inasmuch as it will locate the site of the causal ulcer or demonstrate the fixity of certain portions of the stomach. Besides the adhesive perigastritides with tumor, in which surgical interference is absolutely indicated, the treatment of adhesive perigastritis is surgical when medical therapeutics has been found insufficient. Operation should, of course, be deferred if acute or subacute inflammatory phenomena are present.

News of the Week.

Canada to Have a Federal Department of Health.—A bill has recently been passed by the Canadian House of Commons creating a Federal Department of Health. The bill provides for a minister of health, a deputy minister of health, and an advisory council. The authority of the new department will extend to all matters affecting health within the jurisdiction of the Canadian Government.

Base Hospital Closes.—The $1,000,000 buildings at Eastview, Westchester County, N. Y., which have been used by the United States Base Hospital No. 30, have been turned back to Westchester County. The hospital at Eastview was used largely for the care of convalescent soldiers.

Film on Diagnosis of Tuberculosis Being Shown in New York State.—The New York State Department of Health, through the courtesy of Surgeon General Ireland, Colonel Craig, and Major Stoll, has been able to exhibit a seven-reel film on the diagnosis of tuberculosis, prepared by the Army Medical Department for the special instruction of its personnel. This film has already been exhibited nine times, and it is planned to exhibit it before all the medical societies of the State and to utilize it in connection with special courses of instruction being given by or under the auspices of the State Department of Health. Great good will be accomplished if the men who see these films will try to carry out in their private work the lessons which are so vividly demonstrated.

State Tuberculosis Clinic a Success.—The tuberculosis clinics which are being conducted under the auspices of the State Department of Health, with the cooperation of the State Charities Aid Association tuberculosis committee and the local agencies, public and private, are proving to be highly successful. The clinics have been so well attended that in some instances as many as one hundred examinations have been made in a day, and it has frequently been necessary to call in additional examiners and to extend the clinics to the following day, or to hold a clinic at a later date. Where a second clinic has been held in a locality the attendance on the part of patients and physicians and the number of positive cases found has been double or more times that obtaining at the first clinics. As illustrating what is being accomplished in the way of discovering previously unknown cases, in one series of clinics, among 56 active cases found, 50 had not been known previously to have tuberculosis. It is felt by health authorities that these clinics are providing a service of really concrete, specific, and constructive character.

National Tuberculosis Association Makes Annual Report.—The report of the Executive Committee of the National Tuberculosis Association, which met on Sept. 13 at the Russell Sage Foundation in New York City, shows that the annual death rate from tuberculosis in the United States is more than 150,000 and that there are more than 1,000,000 active cases of the disease in the nation. It is asserted that to combat and prevent the spread of the disease a national campaign is necessary, funds for which will be sought by a ten-day sale of Red Cross seals, beginning December 1. The total of the several state budgets will be more than $6,500,000. The report points out that the death rate of 150,000 a year means the sacrifice of more lives than the United States Army lost the year it was actively engaged in the war. An educational campaign has been formulated for the coming year which is to be extended to every part of the country, with the view of impressing on the people the fact that tuberculosis is preventable and curable. In the proposed campaign special efforts will be devoted to the searching out of unsuspected cases.

Removal of Headquarters of New York Health Department.—By September 25 the headquarters of the New York City Health Department, now at

Centre and Walker Streets, Manhattan, will have been removed to Pearl and Park Streets, across the way from the Municipal Building. The expiration of the lease on the building at Centre and Walker Streets, and the refusal of the comptroller and the Board of Estimate to consider the exorbitant increase of rent proposed by the landlord, necessitated this change. The new headquarters will be used temporarily until the special structure for the Department of Health on Thirtieth Street, between Sixth and Seventh Avenues, is completed. It is believed that the new building will be ready for occupancy in about a year.

Bronx Physicians Organize Union.—It is reported that on September 10 some 250 physicians in the Bronx met to discuss the organization of a union. The object of the union thus far is to demand for physicians an equitable wage from hospitals, insurance companies, and others who employ physicians on salary. The union will probably have affiliation with the American Federation of Labor.

Gifts and Bequests.—Under the will of the late Mrs. Anna Diehl, the Lenox Hill Hospital, New York, is the recipient of a bequest of $6,000.

An Exterminator for Cooties.—According to a report to the lay press, French scientific men have discovered an asphyxiating gas which not only destroys the body louse, but which also acts with soothing effect on the body of the tormented soldier. Professors Bertrand, Broca, Rousseau, and d'Assonville, appeared before the French Academy of Sciences on September 1 and presented their discovery. The name of the asphyxiant is pulverized chloropicrine. The French army will employ this substance extensively in camps and cantonments and will distribute it among its colonial troops.

The Oldest Man in the World.—It is claimed that "Uncle Johnny" Shell who has just celebrated his 131st birthday at Lexington, Ky., is the oldest human being in the world, having been born, according to his belief, in Tennessee September 3, 1788. His eyesight and hearing are only slightly affected and he is still fairly active. His eldest child is a daughter ninety-seven years old.

Noise from Bells and Gongs Regulated.—At a meeting of the Department of Health of New York City, on August 20, resolutions were adopted amending the sanitary code by adding a new section, which reads as follows: "No person shall cause, suffer or allow to be attached to, or maintained in or upon any building or premises any bell or gong, which shall by noise disturb the quiet or repose of persons in the vicinity thereof, to the detriment of the repose or health of such persons. All persons participating in the violation of this provision, either as proprietors, owners, tenants, managers, or superintendents of such building or premises, or licensees or licensors of such electric bell or gong, or otherwise, shall be liable therefor."

Health Department Supervises Sale of Army Canned Goods.—Arrangements were made recently by the Bureau of Food and Drugs of the New York City Health Department to keep all public schools where Government food is sold under continuous observation, so that spoiled or otherwise unfit food will not be delivered to the public. The reports thus far received at the Health Department indicate that the general condition of the food is good.

Red Cross Increases Appropriations.—Extension of the relief activities in western Russia and the Baltic provinces has resulted in the American Red Cross increasing the appropriations for its commission in that region from $270,000 to $500,000. This will benefit both Esthonia and Lithuania.

Hospital Staff and Trustees Dined.—Dr. Albert H. Ely gave a dinner on the evening of September 12 to the medical board and trustees of the Southampton (L. I.) Hospital at his villa on Shinnecock Hills, L. I.

Drive for New Beth David Hospital.—A campaign was started on September 8, to last three weeks, for the purpose of raising $100,000 for the enlargement of the Beth David Hospital at Lexington Avenue and 118th Street, New York. The proposed annex to the present building will accommodate 125 additional patients, bringing the capacity of the institution up to 175 beds. At the opening of the campaign a gift of $5,000 from the Ladies' League of the hospital was announced, and also a gift of $500 from Jacob D. Cohen.

Campaign Against High Heels.—By the courtesy of the Long Island College Hospital, Brooklyn, N. Y., the first reel of a series of moving pictures showing the disastrous results of wearing shoes with high heels and pointed toes was recently filmed on the hospital roof. The volunteer players are patients from the hospital's foot and shoe clinic, and their production will form a part of a nationwide campaign against deforming shoes that is being launched by the Young Women's Christian Association.

Motor Car Deaths Again Increase.—Automobiles in New York State, including the city, killed 127 persons during the month of August, as compared with 97 for the corresponding month last year, according to the report of the National Highways Protective Society. Sixty-two persons were killed by motor cars in the city last month, one by a wagon and one by a pushcart. In New Jersey, last month, automobiles caused the death of 20 persons, compared to 19 in August, 1918.

British Red Cross Distributes Surplus Funds.—The British Red Cross and the Order of St. John have decided to distribute their $5,000,000 war fund surplus among hospitals and other institutions in England and Wales. The grants to be made range from £25,000 for large hospitals to £600 for cottage hospitals. For the establishment of a tuberculosis colony for pensioners in East Lancashire £70,000 is allotted, and grants are to be made to several other branches of tuberculosis work.

Britain Takes Steps to Care for Blind.—The Government Advisory Committee, which has been investigating the condition of the blind in Great Britain, has submitted its report, which makes suggestions for dealing with the problem of the blind. It is recommended that the welfare of the blind be given to a State department, and that the many charitable schemes, many of which have worked to the disadvantage of this class of unfortunates, be extinguished. A uniform system of training for the whole country is recommended, which will do away with the present system of training blind persons in workshops run by charities. As an imme-

diate measure of relief the committee suggests that direct assistance by way of weekly allowances should be made to the blind in their own homes. The blind population of Great Britain has been registered, and according to the data collected number about 30,000. Of this number, one-fifth have been blind since the first years of life, while those who owe their loss of sight to accident comprise about 12 per cent. of the total. About 2,500 of those afflicted are in employment, but their work is of a casual nature, and the trades for which they have been trained are so overcrowded that there is not sufficient employment to keep them above the poverty line.

New State Hospital for the Insane.—Ground was broken for a State hospital for the insane at Marcy, near Utica, N. Y., on Sept. 12, by Governor Smith. The institution when completed will house over 3,000 patients and will be a division of the Utica State Hospital, from which it is six miles distant. In his address the Governor told of the plans which are being prepared by the Hospital Development Commission for a State psychopathic hospital in New York City. This will be the research department of the State hospitals for scientific studies into the causes and treatment of insanity and it will also be used for the temporary care of the less serious cases of mental disorders. It is hoped that it will be possible to provide substantial appropriations each year for a term of years for new construction at State hospitals to catch up with the accumulated overcrowding and to provide for the normal increase of the committed insane which is about 900 a year. The Marcy site comprises 930 acres, and in planning the hospital provision has been made for water supply and sewage disposal so as to avoid any setback such as was encountered in the attempt to establish a hospital at Mohansic.

Influenza Return Expected.—In an official bulletin, under date of Sept. 13, Surgeon-General Blue of the Public Health Service discusses the question "Will the 'flu' come back this year?" He believes it will appear, though not in as severe a form as last winter. He suggests that City officials, State and City Boards of Health should be prepared in the event of a recurrence, and that now is the time to make preparations. Concerning the question of immunity, he states that the evidence is not conclusive, but there is reason to believe that an attack during the earlier stages of the epidemic confers considerable though not absolute immunity in the later outbreaks.

Tuberculosis and Typhoid Fever Decrease.—The records of the New York City Health Department show that though a sharp rise in the incidence of typhoid is looked for during the month of August, there were only 119 cases reported during that month, as against 265 for the corresponding period of last year. Tuberculosis seems also to be on the decline in this city. From Jan. 1 to Sept. 1 of this year there have been 1,026 fewer cases reported than for the corresponding week of last year, deaths from this cause have also decreased in number, there being 549 fewer since January 1, this year, than for the same period of 1918.

Lectures on Venereal Disease.—The Department of Health of New York City announces that a corps of lecturers has been organized by the Commissioner of Health for the purpose of giving talks on sex education to such clubs of women and other associations as may desire them. Those desiring further information concerning the lectures or wishing to make arrangements for them to be given should communicate with Mrs. Vance Cheney, 14 East 36th Street, Manhattan.

Dr. Seymour Oppenheimer has been appointed Consulting Otologist to the Willard Parker Hospital, New York.

The Alvarenga Prize.—The College of Physicians and Surgeons of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $250, will be made on July 14, 1920, provided that an Essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the Secretary of the College (Francis R. Packard, 19 South Street, Philadelphia, Pa.) on or before May 1, 1920. Each essay should be sent without a signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of the competition that the successful essay or a copy thereof shall remain in possession of the college. No Alvarenga Prize for 1919 was awarded.

The New York and New England Association of Railway Surgeons will hold its twenty-eighth annual session at the Hotel McAlpin, New York City, Oct. 20, 1919, under the presidency of Dr. J. S. Hill of Bellows Falls, Vt. A Symposium on "The Modern Treatment of Infected Wounds" will be presented. All members of the medical profession are cordially invited to attend.

Obituary Notes.—Dr. Joseph A. Kenefick of New York, died at Lawrence, Mass., on Sept. 10 aged 58 years. He was a graduate of Harvard Medical School in 1890 and took a post-graduate course at the Vienna Polyclinic and Vienna University. He was a Fellow of the American College of Surgeons, a member of the American Medical Association, the American Laryngological, Rhinological and Otological Society, the American Otological Society and the New York Academy of Medicine. He was formerly assistant surgeon of the Throat Department of the Manhattan Eye, Ear and Throat Hospital, assistant laryngologist at Cornel University, aural surgeon to the New York Eye and Ear Infirmary, and otologist and laryngologist to the New York Foundling Hospital.

Dr. Martin F. Coomes, a graduate of the Louisville Medical College, in 1874, died at a local hospital following an operation, on Aug. 28, aged 72 years.

Dr. George H. Richards, of East Orange, N. J., died at his home in that city, on Sept. 9, aged 56 years. He was a graduate of the New York Homeopathic Medical College, in 1885, and was formerly president of the Board of Health of East Orange. He was for ten years an officer of the New Jersey Society, Sons of the American Revolution.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, August 22, 1919.

Prevention of Venereal Disease.—The question of venereal disease is one of the predominant problems affecting the public health in this country, and one which, on account of the difficulties of solution, is exercising greatly the minds of members of the medical profession and of the more intelligent members of the community at large. It is recognized that the matter must be grappled with promptly and with decision, for the longer an energetic policy is deferred the more serious will the situation become. It is manifestly very difficult to know which are the best steps to take. Direct prophylaxis appears to be barred chiefly for reasons to which attention has been drawn frequently. The proposals of the British National Council for combating venereal diseases, made known recently, have not met with approval. Especially have the suggestions that auxiliary early treatment centers be established been subjected to severe criticism. In a report issued a short time ago by Dr. A. Mearns Fraser, medical officer of health for Portsmouth, the absurdity of the recent suggestions of the Local Government Board with regard to the establishment of auxiliary early treatment centers is dealt with. The practical utility of these establishments is criticised, and the failure of "treatment huts" provided a year or two ago at all army camps and barracks in the Portsmouth district is pointed out. He holds that whatever advantage may accrue from the early application of antiseptics after possible exposure to infection, there is an insuperable difficulty in getting persons to use these "huts," and the same, or superior, results can be much more readily attained by the issue of appropriate outfits. He further goes on to say that "the provision of auxiliary centers in various parts of the town appears to me to be clumsy, extravagant, and futile. To mention one fatal objection only, it is said that such places should be inconspicuous. In the first place, it is practically certain that the character of the place would become known, consequently persons would not care about being seen to enter them. In the second, if it were possible to render them so inconspicuous as to escape public notice they would also be so inconspicuous that persons who want to resort there would not know where to find them." This is fairly cogent reasoning as to the undesirability of "treatment huts," but it provides no argument against early treatment. However, it probably is true that as good results can be more readily obtained by the issue of prophylactic outfits, with the additional advantage that publicity is to a very large extent avoided. The outcry in some quarters against the proposals of the National Council for Combating Venereal Diseases affords further evidence of the extreme difficulty of formulating practical plans to prevent the spread of these infections.

Thirtieth Congress of the Royal Sanitary Institute.—The annual meeting of this institute was held in Newcastle-on-Tyne from July 28 to August 2, and was well attended. There were present representatives of many allied and neutral powers, colonial governments, the Admiralty, the War Office, and the Ministry of Health. There were twenty official meetings, and eighty-three addresses, lectures, and papers were presented. In the absence of Prof. G. Sims Woodhead, the president of the Section of Sanitary Science and Preventive Medicine, his paper was read by Dr. W. J. Howarth. Two sessions were given over to the work of the section. The subject for discussion at the first was the rat problem, and papers were given dealing with the zoology of rats, their relation to disease, and measures for controling the rat population. In this connection it may be pointed out that a bill has been introduced recently into the House of Commons aiming at the destruction of rats and mice. At the second session the treatment and prophylaxis of venereal diseases was discussed. This was the best attended sectional meeting of the congress. It is interesting to note, and adds point to the remarks on venereal disease in the first part of this letter, that the balance of opinion at this session was, on purely constitutional grounds, against the use of prophylactics. Another section which proved very popular was that devoted to the hygiene of maternity and child welfare. The question of the unmarried mother and her child was discussed, and the argument was made that the proper provision for them should be a matter of national responsibility, and not a local burden. At one session of this section the causes of disease and death in the antenatal period and the organization of antenatal hygiene were considered. Attention was drawn sharply to the menace of venereal diseases, and stress was laid on the point that diagnosis should be early and accurate, and that treatment should be immediate, adequate, and easily accessible.

In the section on engineering and architecture, Mr. R. Brown of the Ministry of Health stated that the government was anxious for schemes to be submitted by local authorities as early as possible, and would assist with labor, transport, and material. The government aimed at the erection of 100,000 houses in the first year and 200,000 in the second.

In the section of industrial hygiene, Sir Thomas Oliver, in his presidential address, said that the great thing in industry was to avert "breakdowns," and the length of the shifts must be regulated by the physical ability of the workers. Prof. E. L. Collis, director of the Institute of Preventive Medicine, Cardiff, in a paper upon the effect of occupation on the incidence of pulmonary tuberculosis, stated his opinion that industry is associated with undue prevalence of a type of phthisis which causes death in middle age, and the determining factor may be defective ventilation, either of the workshop or of the lungs.

Port Sanitation.—On July 30, the representatives of port sanitary authorities held a conference. Dr. J. Howard Jones urged an international standard of hygiene of crews' quarters on merchant vessels, pointing out that while under the new housing schemes not more than twelve houses were to be built to the acre, seamen were allowed only 72 cubic feet of space in their sleeping quarters. Rear Admiral Sir Robert Hill, Medical Director General, R. N., gave an address on marine hygiene. He said in part that, although conditions in the navy and mercantile marine differed somewhat, they had one very important point in common, namely, the limited amount of sleeping and working space. He

trusted that the experience gained in the navy would be applied to the amelioration of the merchant service. He considered that it was significant that tuberculosis should remain one of the main causes of invaliding, for it showed that the men's environment must be improved by all means at their disposal. At the conference of Medical Officers of Health, Dr. E. S. Buchanan, discussing the epidemic diseases brought into prominence by the war, drew attention to the fact that eighteen small outbreaks of smallpox had occurred already this year. Only by constant vigilance and by vaccination could the disease be kept at bay. Referring to typhus, he emphasized the importance of its association with famine and misery, and stated that while epidemic spread was unlikely, there were possibilities of local occurrence. With the resumption of pilgrimages to Mecca, the danger of the reappearance of cholera increased. Dr. Neech, Medical Officer of Health of Halifax, in a paper dealing with the after care of sanatorium patients, with special reference to the housing schemes, contended that as treatment of tuberculosis had proved unsatisfactory, efforts should be concentrated on prevention. He consequently proposed a scheme whereby the entire population would be housed in bungalows with open-air bedrooms.

Welfare of the Blind.—The first annual report of the advisory committee on the welfare of the blind, issued by the Ministry of Health, records the work done by this committee up to the end of March last. Some of the recommendations of the committee have been adopted, and are being carried out. These include the registration of institutions, societies, and agencies for the blind and the registration of the blind individually. As for the latter, while the total number of blind persons dealt with in the report is 25,840, it is anticipated that the total will reach 30,000. Of these, the unemployable group is the largest, numbering 11,895, or 46 per cent. of the total number. Of this group, only 2,022 profess to live on their income on earnings, so that the "unemployable" class represents the bulk of the afflicted. While the census returns for Great Britain in 1911 showed a total of 5,526 "occupied" blind persons, the figures given in the report are 6,391; these comprise musicians, singers, farmers, clergymen, priests, schoolmasters, lecturers, and domestic servants. New occupations which did not appear in the 1911 census returns are massage, boot repairing, and poultry farming. There are 1,736 blind children who attend school, including 202 defectives, and there are apparently 362 not at school, of which 147 are defectives. The need for further school accommodation is expressed more particularly for blind children who are also defective. Analyzing the ages at which blindness occurs, the committee states that the largest group is under one year, in which the percentage is 21.4. Of these, 206 became blind within six months of birth, very largely from preventable causes. The hope is voiced that the efforts now being made toward the provision of efficient medical and midwifery attention, antenatal, natal, and post-natal, will continuously reduce this high percentage of cases of birth blindness. With regard to workshops for the blind, the committee urges that any system of payment should be based on trade-union rates of pay for similar work. But in the large majority of cases it is impossible for the blind worker to earn a living at such rates of pay, and the wage would have to be augmented. It has, therefore, been concluded that a fixed sum of 15 shillings ($3.75) a week should be given by way of compensation for the deficit of blindness to all workers earning up to 5 shillings ($1.25) a week at trade union or other standard rates of pay. Where more than this amount is earned per week at such rates, the grant should be reduced by 4 pence in the shilling for every shilling earned over five.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, August 22, 1919.

Post-Graduate Study.—Arrangements are being perfected to make known to American medical graduates the many and great advantages of post-graduate study in France, in Paris and Montpellier especially. It is not generally remembered that many of the great medical discoveries were made in France. Quinine, morphine, and chloroform all were French discoveries; and men like Pasteur, Roux, and Charcot gave the world the benefit of their discoveries, while the Germans were forming syndicates to make millions out of their patented drugs and serums. American dentistry is renowned the world over; but in this branch also the French have progressed marvelously in recent years. The demonstrations made in the United States lately by Dr. Villain have shown this. Indeed there was a veritable revolution in dental methods here during the war. But French medical men are a unit in admitting the superiority of American hospitals in matters of hygiene and in aseptic and antiseptic facilities. Many appeals have been made for the establishment in Paris of a model American hospital.

An American Postgraduate Medical School in Paris.—The project for the establishment of an American school of medicine in Paris is expected to take definite shape at a meeting to be held soon in the office of Mr. Charles F. Beach. Besides a number of laymen, Drs. Tuffier, Dehally, Alexis Carrel, Edmund Burnet, and several other noted physicians and surgeons have been invited. The particular importance of the proposed institution lies in the fact that the stream of American physicians and medical students who, for years, went annually to Berlin, Vienna, and other Central European cities for postgraduate work and research, will be diverted to Paris. The new school is to be under the joint direction of Americans and Frenchmen, and only postgraduates will be received as students. The French medical experts are as enthusiastic over the project as are their American confrères. Some of them admit that the existing Paris medical schools, as at present organized, are not fitted to the needs of Americans. Some of the methods in use are described by practitioners as antiquated. For instance, students are required to pay, in some cases, as much as 1600 francs for the publication of their theses. In the new institution it is proposed to do away with such expensive items. At the same time Americans attending the new school will be able to take advantage of the excellent facilities provided by existing clinics and research institutes.

Study of Typhus in Poland.—Colonel Richard

P. Strong, of the Medical Corps of the United States Army, Medical Director of the League of Red Cross Societies, has arrived in Paris from the headquarters of the League in Geneva to complete arrangements for sending an inter-Allied commission of experts to Poland and adjacent countries to study the typhus situation. The commission will also investigate the presence of other epidemic diseases, particularly cholera, and study the general sanitary condition of the countries with a view to the control and the prevention of the spread of epidemics across Western Europe. The League of Red Cross Societies is sending out this commission at the request of the Polish Minister of Health, and with the approval of the French and British health services, the Office International d'Hygiene Publique of Paris and of Professor Santiliquido (Italy), president of the Inter-Allied Sanitary Commission. The commission will be composed of Colonel Hugh S. Cummin, representing the United States Public Health Service in Europe; Dr. Aldo Castellani (Italy) professor at the London School of Tropical Medicine; Dr. George Buchanan, Medical Officer of the Ministry of Health of Great Britain, and Dr. Visbecq (France). Professor Pumpelly of Cornell University will accompany the commission as secretary.

Rabies.—Cases of rabies observed and treated by the Pasteur Institute in Paris have greatly increased during recent years; 1603 persons were treated last year, and it is thought the 1919 figures will be still higher.

2. Some of the Different Aspects Between Influenza, Pneumonia, and Pneumonic Plague.—S. T. Lee gives a short survey of the plague pneumonia epidemic in China in 1911 and that occurring from November, 1917, to March, 1918, comparing them with the influenza epidemic in that country in the months of March, April, and May, 1918. Discussing the clinical differences between these two forms of pneumonia, he says that in influenza we usually have a longer period preceding the manifestation of lung symptoms, a catarrhal stage, with fatigue and nervousness more marked; when pneumonia does occur it develops clearly as a secondary complication. In plague pneumonia these features are very different; the lung symptoms are primary. A clinical synopsis of the pneumonic plague shows that the patient always complains of headache and loss of appetite, often thirst and nausea, joint and muscle pains, and sometimes epigastric pressure. The temperature varies between 36° C. and 40° C., the pulse is rapid, soft, and fluttering; after these symptoms lasting for twelve to sixteen hours the patient begins to present pneumonia symptoms followed by cyanosis and then cardiac asthenia which leads to death. Only a few hours pass before the appearance of bloody sputum. Single cases of either type of pneumonia during the stage of respiratory hunger may simulate each other very closely. The course of pneumonic plague is much shorter than that of influenza pneumonia; in the former 60 per cent. of the patients died within forty-eight hours, 16 per cent. within twenty-four hours, and 16 per cent. within seventy-two hours. The recovery from pneumonic plague is almost *nil;* only two patients recovered in 72,000 cases, while we see more patients recovering from influenza pneumonia, though the mortality is also very high. The frequent association of pyogenic organisms is found in both forms of pneumonia. In influenza we find pus disseminated in the lung tissue, while in plague pneumonia pus is not formed. This is explained by some as due to the fact that the virus is so virulent as to prevent the activity of other organisms or not to give them time to manifest. In discussing the epidemiological differences between the two conditions, the writer points out that the plague pneumonia epidemics all happened in winter, most marked in January; the influenza pneumonia, in 1918, over the entire world happened in autumn and reached its height in October. Plague pneumonia was limited almost entirely to the laboring classes, and influenza pneumonia, though more severe in unhygienic and crowded places, did not exempt the better classes. In plague direct contact was always necessary for infection, hence one could always trace a chain of infection, while in influenza this was not true. Proper protection against plague pneumonia was absolute protection, while this did not hold in influenza pneumonia. The unsettled bacteriological factors concerned in these diseases is discussed and attention called to the fact that in influenza pneumonia, streptococci, staphylococci, and pneumococci were generally found. Pfeiffer bacilli were sometimes found, while the pest bacilli were never found. Another point of interest brought out is that during the past Suiyan epidemic human carriers of the plague bacilli were discovered.

7. A Note on Segmental Hyperalgesia in Malaria.—D. W. Carmalt Jones, in the course of 1918, made a series of observations on segmental hyperalgesia in trench fever, published in the *Lancet*, Oct. 5, 1918, showing that if a series of light pin pricks are made on the

skin in a direction which crosses a large number of areas of segmental nerve distribution, it will be found in patients suffering from trench fever that three groups of areas are unusually sensitive, particularly as to their borders. The groups are an upper one containing the eighth cervical and first dorsal areas, a middle one containing the seventh dorsal area, and a lower one containing all the lumbar areas. The areas are not found in every case, and in positive cases only parts of these groups may be hyperalgesic, but something of the kind is present in the great majority. He has since examined 120 patients suffering from malaria, and in 70 per cent. of these he was able to find the same areas of hyperalgesia, and they differed in no important particular from those found in trench fever. The areas found hyperalgesic in the malarial cases were: Upper group in 50 per cent. of positive cases; middle group in 100 per cent. of positive cases, and lower group in 59 per cent. of positive cases. The full distribution was found in 10 per cent. of positive cases. It was remarked that these areas could never be demonstrated while a rigor was in progress. In 63 positive cases of trench fever, the hyperalgesia was demonstrated in the upper group in 57 per cent. of the cases; in the middle group in 100 per cent.; in the lower group in 99 per cent., and the full distribution in 35 per cent. The only differences were the more frequent escape of the lumbars in malaria and the consequent reduction in the number of cases of complete distribution. This finding, the writer notes, adds one more to the many likenesses between these two disorders. It is necessary, however, for either disease to be excluded before the presence of such segmental hyperalgesia can be allowed weight in the diagnosis of the other.

10. Vaccination by Subcutaneous Injection.—J. R. Goodall has vaccinated hypodermically approximately 6,000 men and quite a number of officers' children while attached to the Canadian army. As it was impossible to obtain vaccine in bulk, that put up in small capillary glass tubes was used in the majority of cases. These vaccine tubes were first placed in methylated spirit for a few minutes, and then withdrawn singly by surgically clean or gloved hands, the excess of alcohol wiped off, the ends broken off, and the sterile rubber bulb fixed to one end of the tube to blow out the vaccine into a sterile beaker. From one-half to three-quarters of a tube of vaccine was used per individual. Sufficient sterile water was then added to make each injection equal to 1 c.c. The arm was sterilized with iodine and the vaccine injected diagonally with a fine hypodermic needle and syringe into the subcutaneous tissues. The local reaction sets in usually between two and four days and is much like that following antityphoid inoculation and just as variable in intensity. The general symptoms vary in intensity and do not differ from those of ordinary vaccination. In the 6,000 cases quoted there was not one case of infection. This is a clean surgical operation and if untoward results develop they are due to faulty technique. The advantages of the method are that there is no open wound and therefore dressings are not required. The dangers of secondary infection are practically eliminated. The percentage of positive reactions is very high. In only a small percentage of cases the local and general symptoms caused complete incapacity. It is painless compared with scarification. Children undergo the hypodermic vaccination without any difficulty.

Sudden Detachment of Aortic Intima (So-called Dissecting Aneurysm).—Cranston Walker reports the case of a man apparently in good health, who fell down suddenly and nearly died; he recovered somewhat and complained of intense substernal pain and of pain and paresis of the left leg. The latter condition improved. About thirty-eight hours later the man suddenly died. The condition of the left leg was probably due to a portion of the loose intima happening to occlude, completely or partially, one of the main arteries to the limb. When the man was admitted to the hospital, about three-quarters of an hour after the sudden onset of symptoms, the cardiac impulse could not be felt. To percussion the left ventricle was slightly enlarged. The heart rate was increased and the diastole somewhat shortened, but there was no other disturbance of rhythm. The pulse was rapid, exceedingly small, and of such a character as to cause immediate anxiety as to life. The radial arteries were somewhat thickened. The post-mortem examination disclosed the greater part of the aortic intima lying free in the lumen. The aorta was extensively atheromatous and the intima was perforated in several places by atheromatous ulcers. The writer discusses the question as to how intimal stripping can be brought about, giving the various theories advanced to account for it. He maintains that in the absence of bulging of the outer coats, static considerations alone do not provide an adequate explanation, but that the motion of the blood is a significant factor. He says that it may be surmised that if an intima were already undermined and perforated by atheroma, detachment might be accelerated by the moving stream. If tags of intima were partially detached they could be projected into the lumen as flaps, so directing more of the kinetic energy toward stripping. Finally a flap might be thrown directly across the lumen, causing a dam; then the whole of the kinetic energy would be directed to intima stripping, and, as well a powerful pressure factor would be brought into play; the blood pressure below the flap and within the intima would rapidly fall toward zero, while the pressure above the flap and outside the stripped portion of intima would rapidly rise toward ventricular systolic pressure. This would afford a possibility of sudden and violent stripping of the aortic intima, supposing there had been a previous partial undermining and detachment. The writer points out that textbooks on pathology and surgery give the impression that dissecting aneurysm is a familiar spectacle, whereas in some 2,500 post-morten examinations he has not met a single instance. A search of the literature shows that, although one hundred cases can be found, the condition is very rare, being encountered more frequently in museums and textbooks than in practice.

Delusion and Dream.—S. T. Rucker defines a dream as a fantastic play of the unconscious mind, not logically descriptive, but represented by dramatic symbols and mental images. He goes on to point out that ancient people attached great importance to dreams and appear to have understood their language better than we of to-day. The philosophers of ancient Greece and Rome attempted explanations of dreams. Aristotle says, "Dreams are impressions left of objects seen with the eye, and that a small sound exaggerated by slight stimuli, in a dream, becomes noise like thunder." Plato, too, connects dreaming with the normal operations of the mind, and explains them "as prophetic visions received by the lower appetitive soul through the liver." Hippocrates was disposed to admit that some dreams may be divine revelation, but held that others were premonitory of diseased states of the body. Rucker refers to the Freudian theory that a dream is a fulfillment of a repressed or unconscious wish and points out that by patient study the Viennese professor was able to learn how to decipher the strange symbol or sign language of the dream, and in this way formulated his psychoanalytic method of determining the significance of dreams in unraveling the psychic tangles of the abnormal mind. When Freud turned his attention in this direction he

soon discovered that symbolic speech by no means applies only to dreams. It is a common ingredient of the conscious mind and presents itself in folk-lore, in witticisms, in slang, etc. Primitive man made use of symbols as a means of expression; later our logical and descriptive speech was built upon this foundation. In settling upon one single point in the Freudian doctrine, which in importance exceeds all others, Rucker would suggest the presentation of the connection between dreams and psychology and the process of neurosis construction. It has long been suspected that dreams have something to do with insanity; but until the researches of Freud this remained only a suspicion. His ingenuity was the first that succeeded in seizing upon and working out in detail this apparently inaccessible empirical material. He says dreams and delusions spring from the same source, the repressed. Before the repressed has become strong enough to push itself up into the waking life as a delusion, it may easily have won its first success under the more favorable circumstances of sleep in the form of a dream. During sleep, with the diminution of psychic activity, there enters a slackening of the strength of resistance, which the conscious psychic process offers to the repressed. The slackening is what makes dream formation possible. Therefore the dream becomes for us the best means of approach to knowledge of the unconscious psyche. Only the dream usually passes rapidly with the revival of waking life and the ground won by the unconscious is again vacated. In Rucker's study of abnormal psychology he has noticed a striking analogy between delusion and dream. The difference appears to be that a dream is acted out during the unconscious or sleep state and abandons the field when consciousness is restored; while delusion holds sway over the mind during the conscious or waking state and disappears during sleep. Now, if as Freud contends, a dream is the physiological delusion of the normal human being, may not a delusion be the pathological dream of the abnormal human being? Rucker's observations have been that persons who dream have no delusions, and those who are dominated by delusions have no dreams. Therefore dreams may perform an important function in maintaining mental balance by letting the "repressed" find a physiological exit during sleep, instead of pushing itself up into the waking life as a delusion.

1. The Erect Posture.—Leonard Williams points out that man, which here especially includes woman, has paid a high price for the erect posture. So long as the trunk was carried horizontally, the primate's internal viscera rested upon strong supports. The weight of his heart and lungs was sustained by the bony thorax; and the heavier among his abdominal organs, the liver, spleen, kidneys, and stomach, found a sufficiently solid floor upon the floating ribs. The uterus and ovaries rested upon the bony pelvis, while the easily displaced intestines had gravity to aid the anterior abdominal wall in maintaining their mechanical stability, for the primate was higher behind than he was in front. As soon as he adopted the erect posture all this was changed and so changed as to invite, indeed almost to compel trouble. It is upon the abdominal organs that the real toll is levied—stomach, liver, spleen, pancreas, kidneys with their suprarenals, are all deprived of their stable emplacements. They hang; gravity pulls at them, and, just when they are at their lowest, down comes the diaphragm to give them yet another push toward the only haven open to them, the true pelvis. How many are the kidneys which have been found wandering disconsolate and mischievous in the region of the appendix; how many the stomachs which have butted brutally upon the bladder; how many the livers which have fallen from the grace of the costal arch to aid in the downfall of the right kidney? To use the word "uterus" is to suggest retroflexion or retroversion and the same association of ideas compels us to murmur "prolapse" or "congestion" whenever we whisper ovary. But the real desperado in the drama of displaced viscera is surely the large intestine. Originally it was probably a fecal reservoir, in the same sense as the bladder is a urinary reservoir. It may have other functions, all of which were adequately, painlessly and harmlessly performed so long as the body was carried horizontally. But with the erect posture it became transformed from a blameless and probably useful structure into the most serious enemy which menaces civilized man. From a horizontally placed rectangular tubal conduit, allowing a free flow, it became transformed, potentially, at any rate, and in a large number of cases actually, into a vertical mathematical monstrosity with a heavily festooned transverse portion pressing upon the subjacent viscera, suspended between two acute angles, which effectually prevent normal movement; a stagnant, dislocating, intoxicating cesspool for which it is impossible to find a present excuse. The man who is wise as well as upright corrects the effect of his uprightness by wearing a ceinture. Nor is this quite all. In the horizontal position, two most important external organs, the thyroid and the male genitals, were protected; whereas in the erect they are exposed to all the slings and arrows of outrageous attack. That is one side of this interesting ancestral medal. The other is more attractive. Among the simpler physiologico-anatomical results of the erect posture, such as those just referred to, Williams can find but one only which is obviously an advantage. But that is an important one. He means the gain in rapidity of the drainage from the brain and cranial structures generally. In the horizontal position this drainage is sluggish; indeed, when the primate hung his head from fatigue, it must have depended entirely upon the suction action of inspiration, whereas upright man invokes the powerful aid of gravity to assist him in ridding his upper story of effete matters. It is not inconceivable that this difference may explain the distinction between the "intelligence" which we concede to the dog and the "intellect" which we regard as the monopoly of his master. The distinction would be greater still if the master did not so frequently nullify the difference by wearing tight high collars to impede the all-important drainage. A constricted neck means a muddled head; not infrequently it connotes a bald one and a pimply face.

7. Notes on the Common Causes of Persistent Headaches and Their Differential Diagnosis.—Kenneth Clarke draws attention to the prevalence of persistent headaches and refers to their more common causes. Among these causes he comments on a type of syphilitic headache easily overlooked, which is found early in the secondary stage, occasionally even before the appearance of the rash, so that unless some history is forthcoming it may be most difficult to identify, until some sign of organic disease appears. The general treatment is that appropriate to the condition, by mercury, iodides, salvarsan, etc. The headache associated with arteriosclerosis is more readily recognized, and should always be thought of when the patient's age lies in the fifth or sixth decade. His pain is then rarely severe, but is constant and aggravated by stuffy atmospheres. The general condition of people suffering from arteriosclerosis is more or less characteristic; their mental powers deteriorate, their grit loses its spring, and their memory becomes uncertain; moreover, if they consult their doctor on account of their headache they will usually complain of tinnitus or occasional attacks of vertigo. The exhibition of iodides and bromides is the prescribed therapeutic treatment for this condition; perhaps the mixture of potassium and sodium iodides retards most effectively the progress of the disease. Open air, with light diet and careful attention to the bowels, will, in all probability, give the patient more relief than he will derive from drugs. Perhaps, in many ways, the most perplexing form of

headache to deal with from a busy practitioner's point of view is that associated with neurasthenia. Its diagnosis is not always difficult, but in nine cases out of every ten there is associated with it some minor organic defect. The neurasthenic patients very frequently show some symptoms of eyestrain; a minute error of refraction grasps the opportunity of making itself evident, and it may be here remarked that it is the slight errors of refraction rather than the gross ones that are associated in one's mind with frontal or occasionally with occipital headaches. Slight hypertrophy of the turbinates or a small deviation of the septum, themselves often reflex causes of severe headache, become manifest to a much greater extent in the neurasthenic, though their variation from the normal may be very slight. Again, the close association between neurasthenia and chronic intestinal stasis will sometimes make it difficult to decide whether the headache is the result of toxic absorption or whether it is a neurasthenic headache, the neurasthenia itself being secondary to the chronic intestinal stasis. Having once established the diagnosis, the case must be considered on its own merits as to treatment. When there is an associated condition of stasis, this, of course, must influence the treatment. When eyestrain or small defects of the nose or its appendages have become manifest these must necessarily be dealt with, and in that way a large proportion of neurasthenic headaches is relieved, the element of suggestion probably entering in no small degree into the treatment, and with the removal of any organic irregularity many patients will find a cure, possibly a permanent one. The headaches of neurasthenia occasionally recur with a periodicity suggestive of migraine. This is particularly the case in those persons who are also victims of intestinal intoxication. Usually, however, migraine exhibits such characteristic features that it is easy to recognize. The hereditary nature of the disease, the periodicity of the attacks, the prodromes, hippus, and the visual phenomena usually make the diagnosis easy. The part played by eyestrain in the headaches of neurasthenia and migraine has been mentioned, but this by no means exhausts the account of headaches due to these causes. Sir Lauder Brunton once wrote that 90 per cent. of all headaches were due to eyestrain and the remaining 10 per cent. were made up of those due to defects of the nose, throat, or teeth. While discussing the part played by the nose and its appendages, it is right to mention here that headache usually an intense frontal headache, is frequently the first warning of frontal sinus disease. There is another class of headache caused by tight lacing, tight collars and tight hats; particularly in the latter class should be mentioned the modern army cap.

Revue Médicale de la Suisse Romande.

June, 1919.

Coronary Sclerosis in Switzerland.—Orliansky, who is an assistant of Professor Askanazy of Geneva refers to the renewed attention paid to this subject as a result of the discovery that an acute coronary sclerosis is one of the results of war hardships. Since Switzerland was not represented among the belligerents the question arises, has this lesion a counterpart in non-combatants or is the frequency of the find in dead soldiers due to some special factor in warfare, such as emotional strain. Under ordinary circumstances it would be difficult to obtain control material in civilians, but the numerous deaths in the young from influenza, the victims having been largely in robust health when attacked, chance to contribute material of the desired kind. Arteriosclerosis is understood to comprise both hyperplastic and regressive alterations, the latter the so-called atheronecrosis. Various conclusions are derived. Thus 23 per cent. of all cases begin at the age period 18-20. This shows that in Germany both the general incidence and youthfulness of the subjects outrank Switzerland by a large margin. This is singular because during the entire age period 21-30 the incidence in the two countries is identical. This shows clearly that the war has not been a factor in arteriosclerosis among the Germans during this period. It appears—the German statistics are those of Mönckeberg, which are apparently recent—that when the age of 40 is reached there is hardly a healthy coronary artery in Germany. In Switzerland they are found in considerable numbers in the fifth and sixth decades. Some fallacy doubtless exists in these figures which in Switzerland were compiled very largely from grippe victims between 20-40. We thus have to ask if young subjects with beginning arteriosclerosis are not predisposed to death from grippe. This can be settled in time by special research. Women are less often attacked than men with arteriosclerosis, but they suffered more than the latter from the influenza. Arteriosclerosis can begin as early as at the age of 17 years, and can destroy life in a man of 28 years, according to the Geneva statistics.

Finska Läkaresällskapets Handlingar.

May-June, 1919.

Surgery of Cancer of the Stomach.—Elving of Professor Krogius's Helsingfors clinic covers the entire material from 1885 to 1915, numbering 798 patients with sex ratio of 5.5 to 2.5 in favor of the male. Uncertainty of diagnostic methods and impossibility of early diagnosis play havoc with successful treatment. Percentage of antecedent ulcer estimated from 6 to 9. Evidences pointing to chronic gastritis present in 22 per cent. A survey of both inoperable and operable cases shows considerable survival in both, due to mistaken diagnosis. The operations include both the trial laparotomies and gastroenterostomies, both palliative procedures, and survival here also indicates missed diagnosis. By survival means that patients are both living and well. Of those known to be deceased the unoperated survived on an average three months, subjects who underwent trial laparotomy five months, gastroenterostomized patients about eight months, and those subjected to radical procedure 19.9 months. In many of the resection cases the patient was able to resume his usefulness. Of 108 resection cases only six survivals to the limit of 3½ years are recorded. Eleven others lived over 3 years before recurrence set in. At that, the operative mortality was very high, ranging from an unstated high figure in the earlier years to a lower figure—25 per cent.—in more recent times.

Correspondenz-Blatt für Schweizer Aerzte.

June 28, 1919.

Treatment of Epidemic Grippe.—Von Salis, referring to the severe epidemic which appeared in July with its heaped incidence of grave pneumonias in young and robust subjects, and its contagiosity, states that hitherto nothing of the sort had been encountered, save in measles. Medical men were surprised to find themselves powerless to save and became therapeutic nihilists. Nothing of the kind had been experienced in the pandemic of 1889. Then the bronchopneumonias attacked only the elderly and the invalid. The recent epidemic agreed with the older in so far as both exhibited many mild and even insignificant cases. But the severe cases of the two could hardly be said to possess similarity, for the coal tar antipyretics which relieved the older victims aggravated instead of benefiting in the malady of last July. In a series of 267 cases the author made use of electrargol, neosalvarsan, antistreptococcus serum, quinine, and combinations of the same. The attempt was made to fit the medicament to the indication, the serum having been given only in the streptococcus case. Unlike the experience in most other countries, if not unique, is the fact that the second wave of the epidemic was milder than the first; although beginning in October it had extended into the winter when pneumonia would ordinarily be favored. This may have been due in part to the perfection of the serum as a result of time for elaboration. A combination of the latter with quinine seemed especially worthy of trial. Under this management the mortality of the pneumonias was but 15 per cent. in 85 cases during the second wave. If we contrast this with the 59 per cent. of the first wave it is but natural to ascribe some of the improvement to the treatment, for in the first wave the serum was by no means so perfected or available for free use.

Book Reviews.

PULMONARY TUBERCULOSIS. By MAURICE FISHBERG, M.D., Clinical Professor of Medicine, New York University and Bellevue Hospital Medical College; Attending Physician, Montefiore Home and Hospital for Chronic Diseases, New York. Second Edition, Revised and Enlarged. Philadelphia and New York: Lea & Febiger, 1919.

A REVIEW of the first edition of this work appeared in the MEDICAL RECORD of June 17, 1916. The present—second, revised and enlarged—edition differs from the first inasmuch as there is an addition of 100 pages, the author having abbreviated some chapters and added three more, one on tuberculosis of the pleura, one on spontaneous pneumothorax, and one on differential diagnosis of pulmonary tuberculosis. Although there is nothing new offered in these chapters, the whole book as well as the additions show a vast clinical experience and wide reading on the part of the author. The entire subject of tuberculosis—etiology, diagnosis, prognosis, and treatment—is discussed at length. The author's discussion of the relation between influenza and tuberculosis is interesting, although it is far from clear what his point of view is. He says in his first paragraph of his chapter on the subject: "When a tuberculous person is stricken with influenza the outlook is not invariably bad," and in the following paragraph he says: "Clinically, we find that when a consumptive is subjected to an attack of influenza, the process in the lung is liable to extend, and acute exacerbation of the process is likely to occur, which either kills the patient or turns a chronic, and comparatively innocuous, process into a subacute one, and finally to a fatal termination." In other words, anything and everything is possible to the tuberculous when he contracts influenza. The author fails to discuss the statement made by many sanatorium physicians that the influenza bacillus and the tuberculosis bacillus are apparently antagonistic to each other.

Fishberg is strongly of the opinion that tuberculous infection is not acquired by adults and he disregards infection as a factor in phthisiogenesis, particularly in adult life. To the mind of the reviewer it is regrettable that he again quotes Saugmann's statement as authoritative, saying that "It is not dangerous for healthy adults to be coughed at by patients suffering from pulmonary or laryngeal tuberculosis." Even if it should not be dangerous for a healthy adult to be sprayed with tuberculosis bacilli, the question always arises, "When is a man healthy?" There are still too many evidences of infection in adult life to consider precaution in the disposal of sputum superfluous. Fishberg claims that his "unconventional" views on the prophylaxis of phthisis, which he emphasized in the first edition, have been confirmed by the experiences of the various armies in the recent world war. Yet, according to available statistics, the armies and the population suffered most from tuberculosis in countries where antituberculosis hygiene and antituberculosis teaching have been virtually unknown, as, for example, in Russia, Austria, and Serbia, or where antituberculosis propaganda has been in vogue a comparatively short time, as in Italy and France. The English and American armies, where tuberculosis hygiene had been taught, suffered least, and it may be safely said that it is largely due to the continuous and vigorous antituberculosis propaganda in our country, including the teaching that careless expectorating results in the dissemination of the disease, that our morbidity and mortality from this disease have been decreasing faster than in other countries. Fishberg's contention that the decrease of tuberculosis mortality is not due to precautionary measures hardly holds good, and it would seem that he contradicts himself when he says, under caption "Real Causes of the Decline in the Tuberculosis Mortality": "We must never forget in this connection that the modern methods of prevention aim at but one thing: the prevention of infection. And in this they have utterly failed." But in this very paragraph he admits that the inauguration of general hygienic and sanitary measures and the improvement in housing conditions have all been of assistance in the decline of the mortality from tuberculosis.

In this new edition Fishberg has somewhat modified his views of psychic traits of the tuberculous, but he still favors such extreme views as expressed by Saxe, and repeats the unwarranted and cruel statement that "the ascendance of selfishness plays the most important rôle in the moulding of the mental traits of the tuberculous." The author seems to be entirely oblivious to the fact that our greatest authorities on tuberculosis, such as Laennec and Grancher of France, Brehmer and Dettweiler of Germany, Trudeau and King of this country, all were tuberculous, and distinguished themselves by their unselfishness and devotion to suffering humanity. The vast majority of tuberculosis specialists in this country who volunteered and served in the American army in the great world war have been or are still tuberculous. Who would dare to ascribe to these noble men anything but self-secrifice and devotion to high ideals? Aside from these criticisms, the book may well be recommended as worthy of careful study by the specialist, general practitioner, and student of medicine. It is admirably printed and profusely illustrated.

RULES FOR RECOVERY FROM PULMONARY TUBERCULOSIS. By LAWRASON BROWN, M.D. 192 pages. Philadelphia and New York: Lea & Febiger, 1919.

IN this little volume of 180 pages the well-known author gives most valuable advice to patients suffering from tuberculosis. All the vital subjects, such as rest, food, outdoor life, attention to symptoms, the patient's relation to his physician, and directions for his personal and general hygiene, are clearly and precisely given. The mottos and proverbs which head each of the twenty-six chapters reveal a pleasing and rare literary style. Want of space permits us to give only a few of the most striking ones. The motto for the chapter "On Alcohol and Tobacco" is, "Abstinence is as easy to me as temperance would be difficult." From the lengthy motto "On Fresh Air" we quote the following: "The best medicine! Two miles of oxygen three times a day. This is not only the best, but cheap and pleasant to take. It suits all ages and constitutions. It is patented by Infinite Wisdom, sealed with a signet divine. It cures cold feet, hot heads, pale faces, feeble lungs, and bad tempers." "On Cultivating an Outdoor Hobby and On Recreation" it says, "Better to hunt the fields for health unbought, than fee the doctor for a nauseous draught." "On Patient and Physician," "To be trusted is a greater compliment than to be loved." The last chapter in the book gives a table of nearly all the solid and liquid food substances which the tuberculous patient may eat, stating at the same time their protein and caloric values. The author finally adds a generous list of all the well-known popular books on tuberculosis, which he gracefuly designates as: "My never failing friends are they, with whom I converse day by day." Brown's Rules for Recovery may be safely recommended to all tuberculous patients.

THE EARLY TREATMENT OF WAR WOUNDS. By Col. H. M. W. GRAY, C.B., C.M.G., M.B. Aberdeen, F.R.C.S. Ed., Consultant in Special Military Surgery, Late Consultant Surgeon, British Expeditionary Force, France. Pp. 299, with 25 illustrations. New York: Oxford University Press, American Branch, 1919.

FOR three and a half years the author served as Consultant Surgeon in France; the first eighteen months at the base, the last two years with one of the armies. Thus he was enabled to see a great deal of work under all sorts of conditions and could choose, from an almost boundless experience, the methods of wound treatment and operative technique that seemed to give the best results. Since this book was written while the war was still going on, with no definite indication of its early conclusion, and while field and base surgeons had but little time for reading, the author felt that brevity and conciseness were demanded; hence the meat is here, stripped of unnecessary verbiage. When treatment varies at different points from the line to the base, the subject is covered in appropriate sections recognizing these differences. The lessons of the war, as regards thoracic surgery, for example, are well set forth. There is much information that will be equally useful in handling traumatic lesions of peace times, although the book as a whole is essentially devoted to the problems encountered under war conditions.

Society Reports.

AMERICAN THERAPEUTIC ASSOCIATION

Twentieth Annual Meeting Held at Atlantic City, N. J., June 6 and 7, 1919.

DR. DOUGLAS VANDERHOOF OF RICHMOND, VA., PRESIDENT, IN THE CHAIR.

Friday, June 6—First Day.

THE business meeting was called at 9 A M. The minutes of the last annual meeting were read and approved.

Associate Membership.—Under the heading of unfinished business a resolution, proposed at the last annual meeting, was put before the society to be voted upon:

"*Whereas*, The number of active members of the society is limited to 100, and whereas there are a number of men qualified to become members of the society, and who are prevented from doing so by the above numerical limitation, be it resolved that an associate membership be established, whose members shall pay the same dues and be entitled to all privileges, except that of voting."

Dr. O. T. OSBORNE of New Haven asked if it was usual to charge associate members the same dues, if they did not have the vote; and also if (as the resolution was now worded), they could have the privilege of holding office, even if they were not entitled to vote. This should surely be very carefully considered, because as the clause now stood, an associate member could become president.

Dr. THOMAS E. SATTERTHWAITE of New York said that he was very willing to consider any change in the wording that might be necessary. The point to be understood was that this was a convenient way of taking men and holding their applications until such time as they could automatically advance to the regular membership.

Dr. SPENCER L. DAWES of New York asked if an amendment was in order, and if so he would offer an amendment which should read " . . . They shall be entitled to all privileges, except the right to hold office and to vote."

Dr. SATTERTHWAITE said he was willing to accept that change.

Dr. THOMAS REILLY of New York said that he thought the necessity of paying dues should be insisted upon. The men would have the benefits of the meetings and it was fair they should pay dues.

The amendment proposed by Dr. Dawes was seconded by Dr. Osborne, and on being put to the vote, was unanimously carried. The vote upon the resolution as a whole was then taken and the resolution was unanimously carried.

New Members.—The report on the Committee on Admissions was then read by Dr. Thomas Satterthwaite. The following names were proposed as associate members, to take their place automatically as regular members, as vacancies occurred: Drs. John T. Watkins, Detroit, Mich.; E. Bosworth McCready, Pittsburgh, Pa.; A. A. Lescohier, Detroit, Mich.; J. H. G. Upham, Columbus, Ohio; Champ C. McCullough, Washington, D. C.; W. B. Dederick, Hot Springs, Ark.; T. S. Southworth, New York City; R. C. Newton, Montclair, N. J. This list having been considered by the meeting, the secretary was directed to cast a ballot to admit these candidates to associate membership. This was done.

Report of the Treasurer.—Dr. SPENCER L. DAWES read this report, which was referred to an Auditing Committee, consisting of Drs. Barnes, Wilcox and Pottinger, to be accepted at the next business meeting.

Report of the Secretary.—Dr. LEWIS L. TAYLOR stated that three members had been dropped from the list for non-payment of dues, after the customary final notice, and three members had resigned.

The report by Dr. Barnes of the Council Meeting held Jan. 4, 1919, at Dr. Satterthwaite's house, was held over, to be taken up at the final business meeting.

There was no new business to be brought before the society.

Obituary of Robert Coleman Kemp, M.D.—Dr. REYNOLD WEBB WILCOX read the following: "Dr. Kemp was born in 1865, entered Columbia University from which he was graduated at Bachelor of Arts in 1885 and Doctor of Medicine in 1889. During his college days he was noted as an expert on the bicycle and as the writer of many Columbia songs of enduring value. After graduation he served upon the surgical house staff of Roosevelt Hospital. Early in his medical career he became associated with the late Prof. William Hanna Thomson, and decided to limit his practice to diseases of the digestive tract. Shortly after this decision he was appointed Professor of Stomach and Intestinal Diseases at the Fordham University Medical School, and was a successful teacher in his department of medicine until his death, which occurred on Dec. 23, 1918. He was always interested in research and at one time carried on investigations upon shock, while his later work laid the foundations for important advances in the treatment of the diseases of digestion and metabolism. He also devised several methods and instruments useful in the diagnosis and treatment of diseases of the digestive system. He was an acceptable speaker at the medical societies because he always had a message of importance which was based upon a critical study of the literature, careful research in the laboratory, and painstaking clinical observation.

"He was visiting physician in his department to various hospitals, and consulting physician (gastrointestinal diseases) to the Manhattan State Hospital. He was a member of the various local, State and national medical associations. He was a Fellow of the New York Academy of Medicine, member of the Medical Association of the Greater City of New York, of the American Therapeutic Society, of the American Urological Association, and of the American Gastro-Enterological Association. Through his own merits he acquired a large and lucrative practice in his department of internal medicine. The results of his reading, investigation, and clinical observation, were the foundation of his monumental work on the diseases of the stomach, intestines, and pancreas, which immediately won the approval of the profession, and of which the third edition was issued shortly before his death.

"Dr. Kemp as a consultant was respected for the accuracy and therapeutic value of his opinions, as an author for recording the real status of his chosen subject—always giving credit to other workers—as a visiting physician to the wards of humanity for his sympathetic kindness in directing their treatment.

"His home life was ideal, his public services of real value to the world, and his death leaves a void not to be easily filled. Those who knew him well recognized in him not only a great scientist and a distinguished exponent of internal medicine, but an upright, just, and lovable man."

The society then passed into scientific session. Dr. Thomas F. Reilly of New York took the chair during the delivery of the president's address.

Therapeutics and Gastrointestinal Disorders.—Dr. DOUGLAS VANDERHOOF of Richmond, Va., then delivered the presidential address. (See page 487.)

Dr. THOMAS F. REILLY of New York said that it would seem that the last place to look for stomach symptoms was in the stomach itself. Probably two-thirds of the therapeutic measures employed were in connection with stomach symptoms.

Dr. JACOB DINER of New York said he was greatly interested in the statistics presented, particularly those dealing with kidney lesions, as the cause of indigestion. It was often found that when the general practitioner had been using digestants, there was really a nephritis present, usually the chronic interstitial or the parenchymatous kind. In regard to diseases of the teeth, he did not know the type of clientèle dealt with by Dr. VanderHoof, but in New York City, in social work, one dealt with the very poorest dispensary class and it was found that sixty-five per cent. of all complaints was that of indigestion. Upon investigating the teeth large pus pockets and alveolar abscesses were found and if one could persuade these people to have their teeth looked after the indigestion disappeared of itself. In regard to the therapeutics of the question the patient often complained of loss of appetite, if he ate he felt as if had "a stone in his stomach," as he described it.

Loss of appetite was usually treated by nux vomica; eructations by sodium bicarbonate, pepsin, or pancreatin, the physician rarely investigating the type of gastric secretion. It should be stated, however, that pancreatin was subject to a change which ruled all proteins—it was liable to become decomposed. In the natural state the pancreatic secretion was formed two or three hours after meals, in the small intestine, thus, when administred therapeutically, it should reach the small intestine at a time when it was needed, and should be given in pills or capsules (shellac, or gold or silver coated), and thus there would be no opportunity for the remedy to undergo hydrolysis. Indigestion, doubtless, played a great part in medical literature and 50 per cent. of all cases treated were so-called "indigestion." A paper such as Dr. VanderHoof had presented should be brought home to the general practitioner; therapeutics and internal medicine would be greatly improved thereby.

Dr. Oliver T. Osborne of New Haven, Conn., said that this was one of the best papers he had heard for many a day. He wished to emphasize what Dr. Diner had said. He thought, however, that not enough emphasis was laid on the character of the food taken; one should not starve these patients, but undoubtedly many of them were eating wrong. One frequently saw that in order to gain weight, young people tried to put two meals in one, that is, they drank milk as they would water with solid meals; that was putting too much work on the stomach. There were plenty of dietetic mistakes that the physician could stop and clear up the indigestion completely. It would seem, from the results of some of the new laboratory investigations, that pancreatin was not destroyed by the acidity of the stomach; it was found to stand up pretty well against it unless there was an unusual amount of hydrochloric acid present. The giving of digestives, as such, outside of needed hydrochloric acid, was rarely necessary. He would like to ask Dr. VanderHoof what his conclusions were in regard to neuroses. What did he classify as neuroses?

Dr. F. M. Pottenger, Monrovia, Cal., said he was very much pleased to hear this paper, which was well worthy of any organization. He wished to discuss the question from the standpoint of histology and neurology. This was comparatively simple. The innervation of the intestinal tract and stomach was controlled by the sympathetic and vagus. Stimulation of the sympathetic produced decrease or inhibition; stimulation of the vagus produced increased activity of the muscle and glands. The stimulation of the stomach, heart, pancreas and kidney was dependent on the same set of nerves and the stimulation of the vagus nerve caused increased tension throughout the whole gastrointestinal tract. Thus with increase of tension the whole syndrome of appendicitis was produced, as well as that of hyperchlorhydria. The variability of symptoms was a marked feature of any reflex disease; this was because the stimuli did not explode in all individuals at the same time. Thus appendix stimulation might produce increased acid and motility of the stomach or intestinal tract. This might produce irregular contraction and cause pain and gas, or it might produce intestinal stasis, or biliousness, resulting from the stasis. All this might arise from vagus stimulation. Stimulation of the lung in the same way might give rise to disturbance of the stomach, and thus many tuberculosis patients came first to the stomach specialist. In regard to the question of vagotonia in neuroses, many of the profession had now laid aside this finding, but there was something in it all the same. A large group of people were vagotonics, but it would be more correct to speak of parasympathetics. The group of people with neurotic constitutions constituted the vagotonics. Many of these people had a tendency to hay fever, which was not due to anaphylaxis; perhaps they had a tendency to spastic constipation; that was the broader meaning of vagotonia. The anaphylactic portion of the protein molecule produced a stimulation of the vagus right through, and overcame the opposing sympathetic. In toxemia there was another type of stomach disturbance, there was a defect of hydrochloric acid, and in this type the giving of hydrochloric acid was indicated because of the relaxation of stomach tension. The main point in stomach indigestion was to find out whether the case was due to sympathetic or to vagus stimulation, because these two nerves controlled the whole mechanism. The embryological relation of the stomach and lungs was extremely close, and stimulation of one often affected the other. Clinicians had hitherto studied the effects, but the relation of cause and effect was to be found in endocrinological and visceroneurological investigations. With a stimulation enough to produce reflexes there would be marked symptoms. Thus in one appendix very marked symptoms would be shown, in another the stimuli would be ready to explode before any symptoms had been shown. In one case stimuli were adequate, in another not.

Dr. VanderHoof, in closing, said that he had found it very difficult to cover such a broad subject in a short paper. In looking over the table it would be seen that 24 patients were admitted and the diagnosis not made. That did not mean that 98 per cent. of diagnoses in 2,000 cases were correct, but it meant that in 24 cases one did not know what to say. In the case of gastric neuroses, the diagnosis was made with a large question mark. Many of these cases were really organic and not functional. The functional cases were vagotonics. Dr. Pottenger's work on visceroneurology was very valuable.

Water Metabolism of the Organism in Its Relation to the Digestive Secretions.—Dr. John C. Hemmeter of Baltimore, Md., presented this topic. He said he would omit mention of pathological conditions where water excreted from the body was a guide to good or bad prognosis, and would pass on directly to water metabolism. A climb of 1,500 feet meant the evolution of 600 calories and, if one could not perspire, this would amount to a rise of temperature of 8° C. To maintain normal temperature the man must evaporate from the body surface 700 grams of water. This one fact would show the importance of water as a regulator of body temperature and the great amount of water that must leave the body in order to maintain the temperature at normal. Sweating was not caused by the blood that gets to the skin, but by thermic centers in the brain. There were records of men who had no sweat glands, and such men could get on well without exercise. They preferred to move in vehicles, or not to move at all. One such man got a temperature of 106° with exercise of half an hour. Thus the suppression of sweat secretion resulted in serious consequences. The plasma of an ordinary man contained 3,400 c.c. of water and the secretion of gastric juice during the course of the day was estimated at 2,000 c.c. or 2 quarts; saliva 1½ to 2 quarts; pancreatic juice 1½ quarts; intestinal juice was variously stated by different authorities as being from 2 to 6 quarts. The question arose, "Where did the digestive glands obtain the water, and where did the water go to?" A man secreted 8 liters of digestive juice a day and yet had only two or three liters of blood plasma. It had been stated that the drinking of large quantities of water would cause a rise of blood pressure, but it was found that when water was injected into the veins, in quantities as much as 2,760 c.c., in a very few minutes only 260 c.c. remained and the rest was not found either in the blood or in the urine. "Where then, had the water gone?" The blood being a solution of salts, regulated all the osmotic pressure of the body. In pneumonia the body called an amount of salt to the consolidation to bring a water current to wash out the catalytic products of the condensed part of the lung. The body, however, had available water reservoirs apart from the blood which could be discharged again as the needs of the body required it. These reservoirs were the subcutaneous tissue of the skin and the muscles. Thus it was fallacious to assume that the drinking of water would raise the blood pressure in the heart or arteries, because water did not stay in the blood. The work of the reservoirs was to maintain the osmotic pressure constant, and the osmotic pressure in the blood would control the supply in the reservoirs. A thirsty man could absorb water from the digestive tract sooner than a man who was not thirsty, therefore one might suppose that the osmotic currents were under the control of the nervous system, but that as yet was a prophecy. The feeling of thirst began as the reservoirs became empty. It was difficult, however, to judge by thirst in human beings,

because to some pure water seemed to be almost a luxury, and therefore studies on animals gave better information. Two quarts of water might be held in the subcutaneous tissue and not in the blood or the bladder. Emptying the water reservoirs would disturb the water metabolism. The blood suffered condensation when the protoplasm lost water, and thus thirst could cause collapse and even death. It would seem that water played a part in albuminous and fatty metabolism, but it was very uncertain that it exercised any influence in that of nitrogen. Copious fluid was supposed to flush out the organism, but that was doubtful, as were other popular doctrines dating back from antiquity, such as that strong muscle contains but little water, or that meat that contains fat (that is water) is better. Medical diets in regard to water drinking were a fair example of such statements, and it would seem better to let the thirst of the patient govern his water drinking. In regard to hemorrhage, it was found that when hemoglobin was decreased to a certain extent (to one quarter of the normal), one could not safely increase the volume of water of the blood. Thus when a man with three liters of blood lost half of this, the first impulse would be to put in sufficient quantity by transfusion. One should consider, however, that one-quarter of normal hemoglobin had to accomplish oxygenation, and this could be done only by circulating four times as fast as with the normal amount. Giving excessive water by drinking or transfusion would dilute the reduced hemoglobin too much to accomplish oxygenation, therefore these measures had better be deferred for several days.

Peripheral Irritations and Remote Results.—Dr. ROBERT T. MORRIS of New York made this presentation (see page 491).

Dr. C. E. DE M. SAJOUS of Philadelphia said that he was extremely glad to hear the trend of thought that was directing their efforts. This was leading into a channel that he had tried to urge for many years—that was "to get to the bottom of things." The paper which he was going to present on endocrine treatment was on this same principle.

Dr. OLIVER T. OSBORNE of New Haven, Conn., said that this paper contained one of the key notes of the future success of the profession. This matter of never operating, or always operating, for loose kidney was a vexed question. He had sent patients to surgeons for fixation of loose kidney, and had them sent back with the message, "We don't operate for loose kidney any more but we can take out the appendix, which seems to be causing symptoms." One young lady who had been absolutely miserable for four years, and had suffered many things of many physicians, had the loose kidney fastened, and her symptoms absolutely disappeared. On the other hand one knew of cases where one hardly dared to say a loose kidney was there, but one had to, because some other examiner would find it out, and say that Dr. So-and-So had missed it. Whatever one did for the patients, it was necessary to study the physiology, and then one could see what one could do for the pathology.

Dr. J. C. HEMMETER of Baltimore said that in 1914 he was endeavoring to bring out a new edition of one of his works, and he looked up patients who had been subjected to nephropexy. Fifty-two patients were noted who had been operated upon some years before, and of the fifty-two, forty-eight were seen three years after. Of the forty-eight, thirty-nine kidneys moved again, and three were wandering kidneys. The rest were quite movable, much beyond the limits of the normal respiratory excursion, which was physiological, especially for the right kidney. He would think, therefore, that, even assuming a definite promise of relief, the results in these fifty-two cases were discouraging.

Dr. MORRIS, in closing, said that the appendix was often affected by the drag of the loose kidney, thus one could have a syncongestion of the appendix. As Dr. Hemmeter had pointed out, many cases returned. When they first began to do their work, methods for fixation of loose kidneys were not very satisfactory, and the majority of kidneys came loose again after fixation. He then devised a method which he considered very ingenious, and he asked his assistants which method they preferred, his, or another, and was told that they preferred the other. Now, however, if a kidney came loose again, the patient went to another doctor and he did not hear about it. His present method of operating only took ten minutes, and the kidney generally stayed where he put it.

(*To be continued.*)

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-fourth Annual Meeting, Held in Atlantic City, June 16-18, 1919.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 483.*)

Some Observations on Thrombosis of the Coronary Arteries.—Dr. EMANUEL LIBMAN of New York presented this paper. He brought out mainly points regarding the symptomatology and diagnosis. The term "angina pectoris" should, he thought, be eventually dropped and replaced by the term "cardiac pain." There were many causes of pain in the cardiac area. The main causes on the part of the arterial system were, apart from aneurysm, as follows: (1) Hypertension, with or without dilatation of the arch of the aorta and with or without narrowing of the orifices of the coronary arteries. (2) Diffuse dilatation of the arch of the aorta—so-called Hodgson's disease. (3) Syphilis of the aorta, aortic valves, and coronary arteries. (4) Disease of the coronary arteries themselves. The types of disease usually encountered in the coronary arteries were: (1) Diffuse disease. (2) Narrowing or closure of the orifices. (3) Closure of the lumen by atherosclerosis or by thrombosis. Syphilis as an etiological factor was mentioned. The other causes would be taken up at another time.

If a large branch of one of the coronary arteries was rapidly closed by a thrombosis, or was slowly closed, and there was interference with the circulation of the heart because of disease in the collaterals, the usual sequence of events was as follows: (1) Closure of the artery. (2) Infarction of the heart muscle. (3) Reactive pericarditis over the area of infarction. (4) A more or less latent period followed by aneurysm of the heart, rupture of the heart, or death from myocardial insufficiency. This sequence of events had been described by Kernig and Sternberg.

Thrombosis was more apt to be accompanied by gastric symptoms than by other forms of coronary arterial disease. Besides the occurrence of pericarditis, polynuclear leucocytosis was often valuable for diagnosis, because it indicated, in the absence of other causes, infarction of the heart muscle, and that usually meant a coronary closure. When one was in doubt as to whether the symptoms were due to thrombosis, a hint could be obtained by examining the arteries in the lower extremities and finding closed vessels there. The last mentioned fact would help in determining whether the patient, who was suffering from a cardiac disturbance with pain, had had a coronary closure before. Another point of value was the history. If the patient gave a history of having had an attack that was diagnosed as "ptomaine poisoning" or "gastritis," and had afterward had to stop walking because of pain in the chest, then it was most likely that the patient had a thrombosis of the coronary artery. Another symptom of value, Dr. Libman stated, was a peculiar color of the face that he had found in a number of cases of old closure of the coronary artery. It was difficult to describe this color; the nearest description of it having been given by Sansom, who did not interpret correctly what it meant—"it was a leaden tint spread over an earthy hue of skin." Patients suffering from cardiac pain due to diffuse dilatation of the arch of the aorta also had a rather characteristic waxy paleness of the face. Not all patients who had an old standing thrombosis of the coronary arteries developed the typical color, but when it occurred it was almost pathognomonic. Angina sine dolore was believed by the speaker to be a real clinical condition. When thrombosis of a coronary artery occurred in a patient that was not sensitive to pain, pain could be absent. In other words, the so-called angina sine dolore existed because some people were not sensitive to pain.

Three times it had been possible to suspect that the right coronary artery was thrombosed rather than the left. An enormous acute enlargement of the liver, in a case which was evidently one of thrombosis of a coronary artery, seemed to indicate that the right coronary artery was involved. In one case, by the use of some of the points mentioned, it was possible to suspect that the patient suffered from an old thrombosis of the left coronary artery and a recent thrombosis of the right coronary artery, the diagnosis being confirmed at the autopsy. Aneurysm of the heart could be suspected in a patient who was known to have a coronary closure, if at a later period there was found to be a very marked good pulsation of a large area of the left ventricle, with absent or very weak heart sounds.

Dr. Libman finally discussed the question of thrombosis, both of the coronary arteries and the cerebral arteries, pointing out that the tendency to thrombosis was something apart from the tendency to get the arterial disease. Atherosclerosis of the heart and of the brain was very much more frequent than the occurence of thrombosis in such arteries. It was important, therefore, to discover what caused the tendency to thrombosis in certain individuals and what could be done to prevent the condition.

Fixation of the Diaphragm, Following Inflammation of the Pleura.—Drs. H. R. M. LANDIS and H. K. PANCOAST of Philadelphia presented this paper, which was illustrated by lantern slides. The first slide showed right-sided empyema with resulting deformity of the diaphragm, which was tilted up at an angle. In these cases the phrenopericardial angle was often obliterated. The pleura became boggy with pus and degeneration changes followed. The next slide showed the diaphragm completely fixed. In these cases the fixation would probably become permanent as a result of fibrinous union. The third case showed pulmonary tuberculous involvement of the left upper lobe, with the diaphragm fixed on one side, and on the other freely moveable. The shortness of breath in these cases was due to fixation. Compensatory changes were apt to take place on the sound side. A plate of a severe chest burn was shown, with resulting fibrous bronchiectasis fixation of the diaphragm and pneumonocosis. A coal miner's lung showed distortion of the diaphragm, with strands of fibrous tissue from the hylus of the lung. A slide of a potter's lung was shown, with fixation of the diaphragm from deposits of organic dust. In such cases there was no motion at all and the man suffered from typical potter's asthma, very similar to lung phenomena caused by fixation.

Physical Signs Associated with Foreign Bodies in the Bronchi.—Dr. THOMAS MCCRAE of Philadelphia read this paper, which was illustrated by lantern slides. He stated that there were no definite rules as to physical signs in these cases, there being a tremendous difference noted, depending on the age of the patient and the character of the foreign body, the length of time, and character of reaction. The question must be raised, "Were there any signs diagnostic of foreign body, and were these sufficient to justify bronchioscopy?" If the body were shown clearly by *x*-ray, bronchioscopy was justifiable, but in at least 15 per cent. of the cases the *x*-ray failed to show the cause of the lesion, therefore, the study of physical signs was important. The first sign invariably present was the diminished expansion of the affected side. A slide was shown in which a beef bone had been lodged, and within three hours after its removal expansion was equal to that on the unaffected side. The second slide showed a screw, which had been present six weeks with marked signs, diminished expansion, and dullness. The signs might vary from hour to hour, as the foreign body very rarely constantly plugged the air passage. The third case shown had a dental burr present for six weeks. There was diminished expansion and very fine râles, somewhat similar to the crackling of very soft tissue paper being crumpled. The next case was a peanut, which was apparently the most dangerous of all types of foreign bodies. In this instance the bronchus of a child was entirely blocked. The fact that there was sometimes air in the lung was often misleading. The foreign body was apt to set up processes on both sides. Another plate showed a wood screw, present 2½ years, resulting in very marked change and thickening of the pleura and bronchus. This obstruction was very difficult to get hold of. The next was the case of a child, 2½ years old, who had swallowed the steel tip of an umbrella stick. The child was brought to the clinic when it was eight years old. The foreign body had sunk lower and lower. There was very slight pathology in this case. The next case was one in which at an operation an intubation tube had disappeared and it was supposed that it had been passed off by the bowel. Physical signs were severe and all sorts of diagnoses were made, the favorite one being that of tuberculosis. In another patient an atomizer tip was lost and the subsequent physical signs led to a diagnosis of tuberculosis being made. The man spent some time in a sanatorium, when an *x*-ray plate was made and the cause was cleared up. He then remembered he had lost the tip. Signs on both sides were severe in this case, but in many there was very little disturbance. In another case a beef bone had been swallowed nine years before. The patient mentioned this but was told that the bone would have been absorbed long ago. He took a great many remedies for the condition, among which was an autogenous vaccine—hardly applicable to beef bone in the bronchus. On removal there was a very marked stricture found above the bone. In a case where a tack was found the patient showed very marked blowing râles. Jackson in his work had spoken of this sign as the "asthmatoid wheeze." This was heard at the mouth, within an inch or two of the lips, sometimes with expiration, sometimes with inspiration, sometimes both; sometimes being present, sometimes absent. This sign was worth looking for as it was present often when the *x*-ray was negative. It differed from the asthmatic wheeze heard over the lung. Medical men should keep in mind the possibility of foreign body, whenever atypical sounds were heard over the bronchi. Such a lesion did not always cause great disturbance. Metallic bodies gave the fewest signs. Two signs to watch for were: (1) the asthmatoid wheeze, which should be studied as to its diagnostic value; (2) presence of fine tissue paper râles, heard over a limited area of the bronchus, near the location of the foreign body. Finally, the speaker said he thought many foreign body cases had been missed in the past, as they were by no means rare, many of these patients having gone from two to ten years without suspecting the cause of their symptoms. The profession should be more on the alert for this type of lesion.

Dr. H. A. HARE of Philadelphia said that he wished to emphasize the point made as to the danger of a peanut in the bronchus. The toxicity was as great as that of egg white. Another point was that most of the profession were under the impression that efforts should be made early to remove the foreign body. That was true in one sense, but unskillful instrumentation often resulted in much damage. In one such case a man who had got an ink eraser in his bronchus was kept two hours under anesthesia while attempts were made to find the foreign body. He was then rushed to Dr. Jackson, but died shortly after being seen from multiple abscesses of the lungs. These were obviously due to over-manipulation. If the man had been attended to by Dr. Jackson first the body would have been easily removed. The easiest cases had been where the point of the obstruction was directed upwards. Another point was how little damage these bodies sometimes did. One boy, from whose bronchus Dr. Jackson removed a tack, was allowed to go home the next day. After removal of the foreign body the recovery of the lung took place with extraordinary ranidity. It was, however, essential that no one but a skillful bronchioscopist should be allowed to touch these cases.

Dr. H. PLUMMER of Rochester, Minn., said that many cases were seen in which it was impossible to elicit a history of foreign body. In addition to the signs pointed out by Dr. McCrae might be added spasmodic fits of coughing. There was an alternating appearance and disappearance of signs in many cases. The case of the peanut was extremely interesting. He had seen one of a child with a peanut in the bronchus, where there was a temperature of 105°. The moment the obstruction was removed the temperature disappeared. The signs usually cleared up rapidly after

the foreign body was removed. In the case of strictures above the foreign body the easiest method was to dilate the stricture and lift the foreign body out.

Types of Pneumonia Following Influenza.—Dr. W. G. MacCallum of Baltimore presented this subject which was illustrated by lantern slides. In the types of pneumonia seen in Texas, which followed measles the autopsy picture of the lung was very characteristic. There was an interstitial bronchopneumonia with nodular consolidations throughout the lungs and surrounding the terminal bronchioles, associated with empyema. Histological characteristics were great induration of tissues of the bronchial cells and alveoli. This was the result of an effort of nature to barricade against the infection. In other cases there was no such resistance and the lung was everywhere invaded. Hemolytic streptococci were present in all these cases, sometimes associated with the influenza bacillus, which was regarded as a secondary invader. In some cases the latter organism was isolated alone and was associated with acute hemorrhagic pneumonia. In the sudden and dramatic influenza epidemic, which appeared at Camps Lee and Dix, the pneumonia was different. Although there seemed to be some agent in influenza which diminished resistance and led to attack by secondary invaders, the Pfeiffer bacillus was not this agent. Influenza would, no doubt, be proved to be exanthematic in type, like measles or scarlet fever. After resistance was lowered the secondary invaders flourished with extraordinary luxuriance. The types of organisms included: (1) streptococci alone; (2) staphylococci alone; (3) Friedlander's bacillus, not alone; (4) pneumococci alone; (5) influenza bacillus alone; (6) mixed types. The men died after a short illness, without pleural effusion, and areas of boggy, spongy, consolidation were found, which tended to coalesce. The pneumococcus infection produced the most intense lesions.

Encephalitis Lethargica.—Dr. Simon Flexner of New York presented this paper. He said that Dr. Barker had chosen the clinical aspects of this disease and he would deal with the pathological and histological side, especially in comparison with poliomyelitis. Literature from Europe was more or less incomplete, but 160 cases had been observed in detail in England. It was found that the pathological lesions fully explained the clinical manifestations of the disease. The optic thalami, the nuclei at the base of the lateral ventricles and the crura cerebri were chiefly affected. It was distinct from ophthalmoplegic lethargy. The speaker said he had studied ten cases and had derived a different impression in his study of the spinal cord from that recorded in the literature. He thought that if the spinal cord were studied it would be found involved, which was opposed to the usual statements. The cases of encephalitis were apt to drag on for weeks and months and finally terminated fatally, in contrast with those of poliomyelitis in which the patient died in a few days. Comparison of the distribution of the lesions would show that the diseases were distinct, although there were certain resemblances. Another point was the easy inoculation of monkeys with poliomyelitis and the failure to accomplish this in encephalitis. The poliomyelitis lesion in monkeys was similar to that in man. In England a certain amount of experimental work had been done with a form of polyneuritis, which was probably a form of encephalitis. The organisms secured were probably identical with the so-called globoid bodies. After study of these reports the speaker confessed himself sceptical as to the conclusions. It was not known yet that the globoid bodies were the cause of poliomyelitis. The profession should be very slow in accepting results which were not in accordance with the clinical and pathological picture. Dr. Flexner showed slides illustrating wide infiltration of vessels and nervous tissue of the optic thalamus. The ganglion cells were shown invaded with leucocytes. Later a gliomatosis was noted of the injured cord and the nerve cells were destroyed by pressure atrophy. These findings were not characteristic of poliomyelitis. The speaker added that there were many pitfalls and difficulties in obtaining culture material, but until one could get material growing in solid cultures so that what appeared to be the organism would grow into colonies which could be identified microscopically and macroscopically, there remained much room for doubt.

War Neuroses.—Lt. Col. A. F. Hurst, R.A.M.C., gave a short talk on this topic, illustrated by a film. The opportunity afforded for the study of these remarkable neuroses in a military hospital resulted in improving the methods of treatment out of all recognition. It was supposed early in the war that these cases required months of treatment; later it was learned that they could be cured in a single day. The extreme importance of intensive treatment and of not leaving the patient till he was well was learned. Even if the medical men were completely exhausted by a case they persisted until the patient improved. If they got the patient early, improvement was more rapid. One man who had hysterical paraplegia for four years was cured in a few days. Another, blinded at Vimy, was completely cured by reeducation. Another man, buried in a trench cave, showed signs of anterior horn degeneration and the bent back or "muck raker's" back. He was quickly cured. The methods used were mainly those of suggestion, and the mode of development of the ailment was explained to the man in simple language, suited to his comprehension. Often men wheeled in in chairs or couches would be able to leave, walking and pushing the vehicle. One man who had a spasm of the intrinsic muscles of the ear, which persisted during sleep, and was associated with a nightmare of a German going to brain him, was treated. It was found that the spasm disappeared under hypnosis. He was completely cured by suggestion. One man, suffering from hysterical vomiting for weeks was treated by the same method and was able to eat a hearty dinner. The films shown illustrated the remarkable differences in gait and spasms after treatment for a few hours. Often the patient was completely cured the same day.

Hypertonic Gum Acacia and Glucose in the Treatment of Secondary Traumatic Shock.—Drs. Joseph Erlanger and Herbert S. Gasser of St. Louis presented this paper. Their experiments were made to test the effect of hypertonic gum and of hypertonic crystalloids on the blood volume, and the comparative action of various combinations of gum and of crystalloids in animals subjected to standardized traumatization. In all types of experimental shock there was found a reduction of blood plasma. The organism endeavored to compensate this reduction by bringing tissue fluids into the circulation. Microscopic examination would show what had become of the blood that is out of circulation. There was found a marked dilatation of the capillaries of the intestine, which were packed with red blood corpuscles. Moore and Welsh found there was a capillary diaphoresis, contraction of the arterioles. Animals treated with hypertonic gum acacia, and then put into shock, did not develop dilatation of the arterioles. This was due to influence exerted on osmotic pressure by the gum. It was found that gum attracted water into the circulation very slowly so that the maximum blood volume might not be required. This was different from the hypertonic crystalloids, such as glucose, in which the action was almost instantaneous, and the blood volume returned to normal as rapidly. Therefore, if gum plus glucose were given the glucose would be held by the gum. Various mixtures of gum and crystalloids, isotonic and hypertonic, were tried. The crystalloid used was sodium bicarbonate. Some of the animals died, some recovered. A standard of shock from which 48 per cent. died was used. Then 25 per cent. gum acacia with 5 per cent. sodium bicarbonate was used. Instead of 48 per cent., 56 per cent. died, so that it was seen that bicarbonate of soda in this concentration did harm. Then a 2 per cent. solution was tried, with isotonic gum acacia. There was no change in the death rate. Next a 25 per cent. gum acacia, plus 18 per cent. glucose was given in doses of 5 c.c. to each kilo of body weight. This seemed actually to protect the animals. Recovery from shock was the criterion used. The blood pressure was taken in all cases. Injection of this solution was then tried in a case of gunshot wound of the thigh, and during the injection blood pressure and pulse returned to normal. The treatment was tried in splenectomy for Banti's disease; the blood pressure was normal next day, but the patient died four days later and was found to have primary carcinoma of the liver. Various operative cases were treated, such as cranial

operation for osteoma of the skull and removal of a uterine tumor. The number of cases was too small to justify conclusions, but further study on the action of the solution would be made and the cases reported.

The Significance of Prolongation of the Ventricular (Cardiac) Excitatory Process.—Dr. J. MEAKINS of Montreal presented this paper. During the past few years, the speaker said, considerable progress had been made in cardiovascular diagnosis, by the use of the electrocardiograph, especially in morbid conditions of the ventricles. In this study a comparison of the non-pathological conditions was made, to illustrate normal intervals. The Einthoven string galvanometer was used. The ventricular complex was found to occupy about .32 second. The R, S, and T waves corresponded with the ventricular systole. Lesions of the right branch of the bundle of His were shown by the broadening of the Q. R. S waves, but the S, T interval was not prolonged. Heart block could be shown without definite evidence of lesion of the bundle of His, but there was great prolongation of the S, T complex, and the ventricle took a second to contract. Dr. Robinson had mentioned that these lesions might not be permanent. In an elderly lady with distinct myocardial lesion there was prolongation of the ventricular complex, associated with the S. T wave or latter part of the muscular contraction. In twenty-six cases with distinct prolongation of the latter part of the contraction, there was distinct enlargement of cardiac dullness. There was noted an almost uniform occurrence of high blood pressure. A left-sided preponderance was nearly always seen, but sometimes both sides were enlarged. Anginal symptoms—that is, cardiac pain—radiating to the neck and shoulder were noted. Patients also nearly always gave a history of intense exhaustion. The prognosis of the ventricular systole seemed to be good in many cases, but patients without the prolongation of the S, T interval died very shortly. This sign was coincident with increase of myocardial thickness. These conditions might be due to intoxication or to lack of nutrition, as in diabetes. When the diet was improved it was found that the heart contracted with more snap. In TNT poisoning there was distinct damage to the myocardium shown, with prolongation of the ventricular systole. When the prolongation was permanent, the prognosis was serious.

Toe Relative Frequency of Malaria in Persons of Different Ages and Age Groups, in a Large Area of Great Prevalence.—Dr. C. C. BASS of New Orleans presented this paper. A careful study of 31,549 persons of all ages and classes, living in the Mississippi delta, was made during 1916 and 1917, and it was shown that about 49.81 per cent., or nearly half, of all the persons living in this locality gave a previous history of malaria at some time during the year. The presence of malaria was determined by the finding of the parasites in the blood and by the occurrence of attacks. In 15 per cent. of persons giving a negative history of attacks malarial parasites were found on blood examination. Analysis of the blood examination of this large group of people, who were thought to be representative of those in the most malarious regions in the United States, showed that malaria was more prevalent in children than in adults, and thus became a problem of the development stages. Twenty per cent. of the cases occurred in children under five years of age; the highest point was reached at seven years, and the fifth to ninth year period showed the highest average of any five-year period. It was also found that there was 36 per cent. more malaria in colored than in white races. The greater relative frequency of malaria in children, as compared with adults, was indicated by the fact that 50.25 per cent of all the malaria found was in persons under twenty years of age.

The Early Diagnosis of Intestinal Tuberculosis.—Drs. L. BROWN and H. L. SAMPSON of Saranac Lake, N. Y., made this presentation. Ulcerative peritonitis was difficult to diagnose clinically. A patient with a lung lesion who complained of indigestion and constipation, with long continued elevation of temperature, was found to have a tuberculous colitis. A study of the *x*-ray plates taken of this case showed the barium located in the cecum. In seven cases of ulcerative colitis examined six had tuberculous colitis. The diagnosis was founded on hypermotility of the tract, as shown by the *x*-ray, and filling defects which were interpreted as spasm. One case had tuberculosis of the hepatic flexure with a membrane at that point. Often it was noted that when the barium had been evacuated at the end of twenty-four hours there remained an ileal stasis, in which the barium did not pass the ileocecal valve. In almost every case there was spasm of the cecum. Pain, nervous diarrhea, and gas were prominent symptoms in these cases, which were often difficult of diagnosis, but which might be benefited by operation.

A Case of Ayerza's Disease (Chronic Cyanosis, Chronic Dyspnea, Erythremia, Enlargement of the Liver and Spleen, and Hyperplasia of Bone-Marrow), Associated with Syphilitic Sclerosis of the Pulmonary Artery.—Dr. A. S. WARTHIN of Ann Arbor, Michigan, presented this case, observed clinically over a space of five years in the clinics of Drs. Dock and Hewlett at the University of Michigan. This case was at first supposed to be one of mediastinal tumor, as the *x*-ray showed a large, well-marked shadow above the heart. This did not increase in size. The patient was a laborer. He showed chronic cyanosis and polycythemia. The blood count showed seven to eight million red corpuscles. Later the case was recognized as one of Osler-Vaquez disease. The clinical course was characterized by attacks of angina hypercyanotica, cyanosis, increasing weakness, drowsiness, edema, asthma, dyspnea, enlargement of the spleen and liver, multiple teleangiectasis, and constant erythremia. The man was fairly comfortable for some time, but finally developed large spleen and liver, very marked somnolence, which was in accord with the Spanish description of the disease. The patient came to autopsy, which was performed by the speaker. The findings were: Extreme atherosclerosis of the pulmonary artery and all its branches, extreme dilatation of the right heart, fibrosis and emphysema of the lungs, extreme angiectasia of the entire vascular system, enlargement of the liver and spleen and hyperplasia of the bone marrow. The microscopical examination showed the presence of a typical syphilitic mesarteritis of the pulmonary artery and aorta, chronic fibroid myocarditis, pancreatitis, orchitis, leptomeningitis, adrenal infiltration of plasma cells, and also changes in the stomach wall of a syphilitic character. The writer said he believed the Osler-Vaquez syndrome in this case to be the result of a diffuse syphilitic process in the pulmonary artery and all of its branches, resulting in chronic dyspnea and cyanosis, to which the erythremia was the secondary compensatory process. The history of the case showed it to have gone through, first, a pulmonary evolution (asthma and dyspnea) and later a cardiac (intense cyanosis, angina hypercyanotica, congestion of all organs, multiple telangiectasis, hemorrhage, edema, etc.). The case, therefore, corresponded in all respects to those first described by Ayerza in 1901, in which occurred the Osler-Vaquez syndrome of chronic cyanosis, erythremia, and enlargement of the liver and spleen, as secondary to sclerosis of the pulmonary artery. In Spanish-American literature this clinical and pathological complex was known as "Ayerza's Disease" or "Cardiacos Negros." Such cases presented a definite clinical evolution of two stages, a prolonged pulmonary stage and a shorter cardiac one. Radiography showed an enormously dilated right heart, heart low with elevated rounded apex above the shadow of the left ventricle, a small convexity due to the dilated pulmonary artery, and above this the normal shadow of the aorta. In the case cited, the shadow of the extremely dilated pulmonary artery and that of the aorta were mistaken for a mediastinal tumor. The Osler-Vaquez syndrome was not a morbid entity, but a syndrome of varied etiology. From it one could separate one group of cases in which the syndrome originated in sclerosis of the pulmonary artery, or Ayerza's syndrome. The case reported was the first recorded in this country and in the English language.

Dr. EMANUEL LIBMAN of New York said that one of the first cases of diffuse atherosclerosis of the pulmonary arteries was described by Neubauer in a case that had been mistaken clinically for a congenital defect of the heart. According to the literature, atherosclerosis of the pulmonary arteries was not infrequent in Bengal.

Dr. WARTHIN said that none had been described with general polycythemia.

Animal Experiments with Bacteria Isolated from Influenza and Pneumonia.—Dr. E. C. ROSENOW of

Rochester, Minn., presented this paper. The lungs of guinea-pigs were studied, after injection of cultures from influenza cases, and after intraperitoneal injection. Some of the cultures had extraordinary virulence. Insufflation often killed in fifteen minutes. This appeared to be from anaphylactic shock. A study was made of injections, up to the sixth animal passage, and it was found that the power of the organism diminished very rapidly. In the early part of the epidemic there were more fatalities. The later cases were those of true bronchopneumonia. Slides made of experimental lesions showed great exfoliation of the bronchi and extreme dilatation of the alveoli of the lung. Many of the lung sections were bare of epithelium, which had desquamated. Most of the organisms (diplococci) were in the alveoli and there was little tendency to invade the pleura. Hemolytic and green-producing streptococci were found in the lungs. The latter might probably play a part in the production of the symptoms of the patient in the early days of the disease. It was found possible to produce the pathological picture in the guinea-pig, and also to type the sputum in influenza, the same as in lobar pneumonia. There was one highly agglutinable strain found.

The Production of Bright's Disease by Feeding High Protein Diets.—Dr. L. H. NEWBURG presented this topic. He said that the clinician had so far been unable to name the etiological factor of Bright's disease, and the causes suggested by investigators had so far accounted for only a minority of cases. The chief business of the kidneys was to rid the organism of the end products of protein metabolism. Could it not be true that the kidney could secrete a certain amount of nitrogenous matter for an indefinite period without suffering harm, but that it would be injured if the quantity of some or all of the nitrogenous substances was increased and kept at the higher level for some time? Thus experiments were undertaken on animals fed with high protein diet and the groups were typed according to the protein used. The following results were obtained in rabbits: When rabbits were fed several egg-whites daily, evidence of renal injury was very quickly and constantly noted. With continuance of the egg-white feeding, acute nephritis resulted. However, when the nitrogenous metabolism was increased by means of casein, the animals suffered no renal injury from an intake of 15 grams daily; when the daily ingestion of casein was 30 grams, the nitrogen metabolism was about three times the normal and well marked deleterious effect on the kidney was produced. Another group of animals were fed on soya beans for months regularly, and these developed chronic nephritis regularly and frequently died from it. The nitrogen metabolism in this instance was about twice the normal. It was found that the renal lesion produced by feeding high protein diets was not caused by the passage of too much urea through the kidney. It would seem that the kidney injury was related to those digestion products of protein which vary both quantitatively and qualitatively with the type of protein ingested.

A Study in War Nephritis (Urinary Tract Purpura): A Probable Entity.—Drs. W. G. LONGCOPE and J. P. PETERS of New York presented this paper, which was read by Dr. Peters. These cases of nephritis were studied at an American army hospital. One distinct condition was found, consisting of multiple submucosal hemorrhages in the bladder wall. Twenty-five cases were seen which differed from ordinary nephritis. Edema and dyspnea were lacking. There were profuse hematuria and pyrexia of a variable type. No etiological factors were found. The disease was completely developed in forty-eight hours. There were prostrating headache, hematuria, dysuria, pyrexia, pains in the back and the legs. The pains differed from those of vesical colic. There were no hemorrhages in the skin, no cardiac involvement; the blood pressure was normal; occasionally there were nausea and vomiting. Jaundice and enlarged liver were not present. Leucocytosis was not noticed. Hematuria was noted as late as the sixty-fourth day. Cystoscopy showed multiple hemorrhages on the posterior and lateral walls of the bladder. Blood came from both ureters. Specimens from the hemorrhagic spots were obtained, but nothing suggestive of inflammatory processes was found. There were two atypical cases, which later developed hemorrhages in other parts of the body. No pyogenic organism was isolated. The evidence that a clinical entity existed was purely circumstantial. The cases formed 14 per cent. of the entire number. Purpura limited to the urinary tract was sufficiently remarkable to command attention. It was possible that these cases occurred in civil life.

Third Day—Wednesday, June 18.

Dr. Osler's Influence on American Medicine.—Dr. G. KOBER of Boston, Mass., presented this topic. He said that on July 1 Sir William Osler would reach his seventieth birthday. This paper was offered in sincere appreciation of his work in the art and science of medicine, in gratitude for the inspiration which he had furnished, and in the hope that his example and influence would be a stimulus to the younger generation of medical men. Osler's career had been marked by successful efforts to uphold higher medical education and his work had been fruitful in compelling medical legislation which had an important bearing on American medicine. Enumerating the activities of Dr. Osler, the speaker said that his text-book on the principles and practice of medicine was on the bookshelf of nearly every English-speaking physician. He was an active member of many medical societies and fostered their advance, because he considered that a medical society was a medical school. In 1885 the plans for the commencement of the Association of American Physicians were laid by him, and in June, 1886, the first scientific meeting took place. Even after his departure from this country he was present at many of the meetings. In 1894 he was elected president and gave as his address the topic, "How Far Has the Association Realized Its Aspirations in the Advancement of Medicine?" He stated that the association would play no part in medical politics, nor did it ask what part of the country its members came from; what was demanded was that its associates should have done good work and would do more. The nine volumes of transactions therefore were the repository of the best of medical literature. The subjects therein reviewed included studies on the heart and blood vessels, on infectious diseases, on tuberculosis, on pancreatic disease, and on the endocrine system. Osler felt that readers had often failed to grasp the scope of the association, and that there was a scarcity of pathologists and bacteriologists in the country. He insisted that this was a working society and that when the members failed to attend the meetings they would best serve the interests of the association by retiring from its roster. He exercised a strict but just censorship in regard to the membership list. He was as popular in the association as a teacher as he was in the medical schools. Men much older than he were glad to sit at his feet and listen to him. He was one of the enthusiastic founders of the National Association for the Study and Prevention of Tuberculosis. He had a real and sincere interest in the achievements of American medicine, and it was not necessary to say more before such an association as this as to his really great and beneficent influence.

Dr. E. P. JOCELIN of Boston, Mass., said that he had a lively recollection of a telegram he received from Dr. Osler, some seventeen years ago, announcing his election to the Association of American Physicians, and signed Sir William Osler. Doubtless many received such telegrams, which he always attended to personally. It would seem fitting that this society should show its appreciation on his birthday of his services, and he wished to propose that the association send a cablegram or letter, timed to arrive on that date, and to read as follows: "The Association of American Physicians, in grateful recognition of the distinguished services of Dr. Osler, as its founder in 1885, and because of his beneficent influence on American medicine, sends sincere congratulations on his seventieth birthday, and hopes that his days of activity will still be many, to complement a life so full of fruitful achievements and work in the service of humanity."

Dr. H. SEWALL of Denver seconded this motion, which was carried by a rising vote.

Functional Diagnosis of the Pluriglandular Syndrome in Acromegaly.—Dr. C. P. HOWARD presented this paper. The necessity was apparent, he said, for outlining tests for the functional activity of the endocrinal glands. The occurrence of five cases of glandular disturbance in a small clinic justified the testing and carrying out of

accurate measurements. The test of sugar tolerance had been thoroughly studied and seemed to be the most reliable. The profession, however, had realized the difficulty of interpreting sugar tolerance. He had endeavored to tabulate results in this respect. In one case he had found the sugar tolerance greatly increased up to 300 grams; in the other cases it was diminished and an active glycosuria was present. The use of application of adrenalin solution in the conjunctival sac was then tried, with the eye closed for five minutes previously. Pallor of the conjunctivæ occurred which lasted from ten to twenty minutes in the normal individual. Fifteen normal controls were tested and the reaction lasted from ten to thirty minutes. It was thought that any deviation from this signified disorder of the adrenalin secretion of the body. Five acromegalic cases were then tried; in two cases the reaction was normal; in three it was much prolonged. In two cases of dystrophia adiposa genitalis and in two cases of hypopituitarism the reaction varied considerably. The second adrenalin test suggested was to take records of both systolic and diastolic blood pressure after the injection of 0.5 c.c. adrenalin solution subcutaneously. Falta had stated that this would be followed by prompt increase of blood pressure. Fifteen normal controls were used to test the polyglandular system. The maximal increase was 42 mm., the minimal 3 mm.; the average increase was 20 mm. mercury. This series showed practically nothing. In one case there was a sudden fall of 14 mm. There was no explanation for that. Chesby had studied the effect of adrenalin on the blood picture. He found that 0.5 c.c. of the solution would produce a well defined leucocytosis, with increase especially of the polymorphonuclears. In the present tests twelve controls were studied and a definite leucocytosis found in eight. In four of the controls there was no increase but a decrease two hours later. One case of leucopenia Chesby had considered hypoadrenalism. In one case of adiposa genitalis Dr. Howard said he got definite leucocytosis, but there was a pelvic cellulitis which might account for this. Chesby had suggested putting pituitrin in the conjunctival sac. This was tried with normal controls and it was found that there was a definite blanching for twenty-five minutes, but in some persons none took place. In one acromegalic case blanching lasted forty-five minutes. Experiments were tried as to the effect of pituitrin on the blood pressure, and as irregular results were recorded as with adrenalin. The effect was slight in all but one case, which was marked. There was a slight increase of leucocytes. Very little evidence was obtained as to abnormal cases. In one case of dystrophia adiposa genitalis a definite leucopenia was found. One conclusion was drawn: a case of secondary hypopituitarism might result from increase of cranial pressure. In a case of tumors of the solid area of the brain the sella turcica was compressed, the posterior and anterior clinoid processes were gone, the base of the sella was thin and microscopical examination of the gland showed hemorrhages into the gland. There was decrease of sugar tolerance. It would seem that adrenalin might be administered in hypofunctional cases. The tests with adrenalin and pituitrin, however, were of doubtful value in both normal and pathological cases. Injection, either of the whole gland or of two lobes, appeared to exert no influence on the symptompathology of the disease.

Dr. H. PLUMMER of Rochester, Minn., said that the increased energy output of the thyroid increased the metabolic rate. Diastolic pressure dropped, systolic pressure rose, but all variations were noted depending upon fatigue in the heart and the constriction of the peripheral arteries. In hyperpituitarism there was increased metabolic rate. A series of cases, not yet reported upon, were worked out at Cushing's clinic. In hyperthyroidism with a high toxicosis there was high blood pressure. In borderline cases this was not significant.

The Function of the Thyroid Gland.—Dr. H. S. PLUMMER of Rochester, Minn., presented this paper. A study of the thyroid hormone was organized in 1915 from various data collected on the subject. It was found that thyroxin was active in all the cells of the organism, probably acting as a catalyst or a quantum of potential energy available for energy transformation on the stimulation of the cell. The latter varied with the thyroid content of the cell. In hyper- cases there was excess; in hypo- cases a deficiency. Each cell of the organism was compared to the cylinder of a gas engine: energy varied with the frequency of excitation. There was little excitation with a low basal rate. In muscular work and in hyperthyroidism a high basal rate obtained. In the first the metabolic rate was above normal, in the second the basal rate was above normal. Response of the cells varied with the rate of stimulation. This theory might receive modifications, but it would serve as a basis for investigation. Difficulties encountered in the study of hyperthyroidism were many and it was hard to coordinate various thyroid states. Energy transformation worked smoothly when the stimulation and the quantum for discharge were in proportion. The cells, however, could be gradually trained to stand increased stimulation, which was shown particularly in cardiac action. In the hypo-stimulated cases the metabolic rate was 15 to 20 per cent. below normal, as in high-grade myxedema. When the rate was 30 per cent. below normal no thyroid gland was found. In cases with large colloid goiter the gland had hard work to make the required amount of thyroid. If more than a normal amount of thyroid were given in these cases the gland would gradually quit work. There was a phase before the gland could adapt itself and the body could get rid of the excess. Ordinarily about 1 mg. of the thyroid hormone was the daily requirement. In one case of adenoma of the thyroid, namely, pure hyperthyroidism, there was 15 mg. of thyroxin in the body. Upon introducing thyroxin into the body there was, on an average, a 3 per cent. rise in metabolic rate for every 1 mg. of substance introduced. In myxedematous cases this was shown to maintain a level to about the eleventh day; it then began to drop. These facts were very spectacular. In one farmer, a high-grade myxedematous case, who was unable to walk, the administration of one dose enabled him to go back to work and to put in his spring crops. The wear and tear on thyroxin probably depended upon the number of times it was put into chemical reaction. It was determined by the energy output for the twenty-four hours and not by the metabolic rate.

Chemical Identification of the Thyroid Hormone.—Drs. E. C. KENDALL and H. S. PLUMMER of Rochester, Minn., presented this paper, which was read by Dr. Kendall. In 1915 the isolation of the thyroid secretion in crystalloid form was accomplished. Since then efforts had been directed to the accumulation of the substance. Structural and empirical formulæ were determined and later preparations were made to prove the formulæ. Synthetic formulæ had now been made and the substance was found closely related to the amino-tryptophan group. With the isolation of a single crystalline substance, quantitative measurements were possible. There were two points to be considered: (1) What the substance did in the body; (2) how was this action brought about. Thyroxin was really an amino-acid. The word thyroxin was an abbreviation of "thyro-oxy-indol." From a study of the absence of this substance, one was justified in saying that thyroxin was not essential to life. Its action was superimposed upon that of the amino acids of the body. With complete absence of thyroxin, however, there was a lack of flexibility in the energy output, as seen in myxedematous individuals. Probably there was one part of thyroxin in ten million in the blood, two parts in ten million in the tissues, and three parts in ten million in the liver. The equilibrium existing in normal individuals lay within very narrow limits. There had to be close relations between the amount in circulation and that in the tissues. There was less than one-third of a grain functioning in the entire body. The question as to its mode of action was examined, as to whether iodine was necessary to its function. It was found that the N H group was essential to the action of the substance. Tests were made upon tadpoles to see which part of the substance exercised influence in metamorphosis, whether the organic nucleus or the iodine. It was found that metomorphosis was influenced by the acetyl derivatives and that thyroxia, therefore, had a closer relation to the acetyl nucleus.

Experimental Factors in the Compensatory Hypertrophy of the Thyroid Gland.—Dr. LEO LOEB of St. Louis presented this subject. The experimental work

undertaken had a bearing on clinical practice. After extirpation of part of the thyroid, the remainder changed in appearance and became similar to that in exophthalmic goiter. The work of Kendall would seem to need confirmation. Halsted had worked on hypertrophy of the thyroid gland, but his results were very contradictory and the evidence was incomplete. He used dogs for his experiments, and as dogs were frequently subject to goiter one could not be sure that his results were not obtained in goitrous dogs. There were discrepancies between his earlier and his later work. It had been stated that if iodine were used in the dressing of the wound very small amounts of iodine would prevent hypertrophy of the gland. The present experiments were therefore conducted in guinea-pigs. If almost the complete thyroid were extirpated, exophthalmos was produced. There was definite relation between atrophy and hypertrophy of the gland, to the amount extirpated. Halsted found that if he extirpated the thyroid in pregnant dogs the offspring showed hypertrophic glands. This effect was not obtained in guinea-pigs. Meat feeding was tried and this produced hypertrophy in three weeks. Tethelin, or the active principle of the pituitary body, was used, and this had no influence on the thyroid gland. The effect of iodine in preventing the hypertrophy of the gland was studied, and it was found that even large amounts of iodine did not prevent hypertrophy. On the other hand, guinea-pigs fed with thyroid tablets showed diminished size of the normal cells of the gland. In a few experiments thymus gland was used, and it appeared possible that the thymus had a similar effect on the thyroid. It would seem to be useful, therefore, to have some method which could be used for testing thyroid function and changes characteristic of exophthalmic goiter.

Dr. H. S. PLUMMER said the feeding of the thyroid and not getting hypertrophy was perfectly logical. What one would logically expect was that the thyroid gland would atrophy if thyroid was fed long enough. Also, if one gave insufficient food long enough and used less thyroid, one would get atrophy.

Dr. LEO LOEB said that he did not go into those details, but he was in agreement with Dr. Plummer. If guinea-pigs were starved for several weeks, however, there were not the same changes in the glands as after feeding thyroid tablets.

Cancer of the Pancreas.—Dr. T. B. FUTCHER of Baltimore presented this paper. Fifty-eight cases had been noted among 41,000 patients admitted at the Johns Hopkins Hospital. The speaker had studied thirty cases where the diagnosis had been confirmed by exploratory operation or by autopsy. Twenty-one were in males, nine in females. Most were in the fifth decade of life. Pain was a prominent symptom in all but six cases and was located in the upper section of the abdomen. Jaundice was the most constant symptom. This was progressive, persistent, and intense. One patient was almost black and had the appearance of argyria. A palpable tumor was present in twelve cases, in the apex of the epigastrium; this did not descend on deep inspiration. A distended gall-bladder seemed to be an important diagnostic physical sign, and was different from the blocking of the common duct by stone, which did not cause distention of the gall-bladder. In nearly all cases there was enlargement of the liver due to jaundice, but this lacked the features of ordinary catarrhal jaundice. This was sometimes due to lack of function of the pancreas, and acholic stools were noted with excess of fat. Such stools were present in twenty-two out of thirty cases. In two there was actual fatty diarrhea with twelve to fourteen large fatty white stools in twenty-four hours, due to the growth shutting off the pancreatic ferment from the intestinal tract. Glycosuria was present in 10 per cent. of the cases. This symptom did not occur as often as one would expect. The tumor was usually situated at the head of the pancreas; one was in the body. Eight were primary cases, two were secondary to carcinomata of the stomach and gall-bladder respectively. These were adenocarcinomata. There was one case of hemangioma endothelioma. Treatment in these cases should be begun in time to prevent invasion of the other glands; it should be palliative to prevent emaciation and relieve symptoms. Pancreas might be tried with calcium carbonate to help with the diarrhea. The clinical picture showed pain, persistent intense jaundice, great emaciation, distended gall-bladder, palpable tumor and acholic stools with fatty diarrhea.

Dr. BOND said that he had seen one case with no symptoms excepting general weakness. There was no obstruction of the gall-bladder and no pain.

Dr. R. FITZ of Boston said, in regard to the diabetic problem, that he did not think these cases with glycosuria had true diabetes. A peculiarity of these cases was that it was difficult to mark the development of acidosis.

Dr. FUTCHER said that the blood-sugar was not tested He did not know what the findings were in reference to acidosis.

The Autopsy Service of the American Expeditionary Force.—Dr. L. B. WILSON presented this paper. At the beginning of the war there were but twelve men in the service who knew how to properly perform an autopsy. Less than 200 post-mortems were performed, and in May, 1918, only about 26 per cent. of the patients dying came to autopsy. The necessity was realized of inspecting and increasing such work. By May, 1919, 14,000 autopsies had been performed and there were 450 men signing the protocols. These protocols were now stored in Washington. They covered gunshot injuries, gas-poisoning, typhoid following vaccination, influenza, pneumonia, etc. Two hundred of the men whose work had been graded as good would soon be back in the United States, because their work was equally needed here. The success of the work was due to a frank recognition that it was an inspectorial service. It was made a routine, and departures from routine required explanation. The percentage of autopsies was pushed to 92. With the lower mortality following the armistice it dropped to 80, but was pushed back to 95 again. There were no hospitals in the United States that could approach these figures, except those hospitals which required permission for autopsy as a condition of admission. Very few hospitals had more than 10 per cent. of autopsies. The attitude should be taken in this country that the work of the physician needed this inspectorial service that the truth might be known concerning his worst errors. If permission were asked frankly on this basis, much greater success would be obtained than had been in the past.

A New X-ray Sign of Perinephritic Abscess.—Drs. H. M. FUSSELL and H. K. PANCOAST of Philadelphia presented this paper, read by Dr. Fussell. This sign had not been found mentioned in the literature, but it was possible that references had been overlooked. A patient was seen who complained of pain in the left lower chest, with fever of a septic type. Physical examination, except for pain in the left lung, was negative. He gave a history which simulated peptic ulcer. The speaker had volunteered the diagnosis of perforated ulcer, with collection of pus. The *x*-ray plate showed a picture of gallstones. He was sent for fluoroscopic examination, but no fluid was demontrated. After ten days he was sent to the hospital for further complete study. He had pain in the left loin and slight tenderness, but no localized signs of gallstones. He was again fluoroscoped, and Dr. Pancoast stood by him and shook him from side to side. The diaphragm was normal when lying down; when he stood up it was flattened, and when he was shaken it was wavy. This phenomena would not be of value on the right side, where the liver was interposed between the kidney and the diaphragm. In this case the surgeon thought that the gallstones were the cause of the pus production. He proceed to open the loin and found the kidney surrounded by 200 c.c. of pus. The patient made an uneventful recovery. Some months later he developed typical gallstone symptoms. Operation was done and search was made to see if the pus had originally come from the gallstones, but it was found that the pus had come from a primary perinephritic abscess. This wavy appearance of the diaphragm on fluoroscopic examination was a valuable diagnostic sign in early detection of perinephritic abscess.

Trench Nephritis at a British Hospital in France.—Dr. R. FITZ of Boston made this presentation. The acute type of nephritis seen opened up a very interesting field for study of kidney disease. There were definite clinical characteristics: bronchitis, dyspnea, sudden onset, uremic manifestations, and renal dropsy. The mortality was low, being but 5 per cent of all medical cases. It was most common between 30 and

40 years of age and occurred in men who had been in France for short periods of time. An endeavor was made to discover epidemic foci, but it was spread over an immense territory. The dyspnea was a very marked characteristic, but it was cardiac, and not mechanical. Acidosis was not marked, but slight acidosis was constant. This did not bear any particular relation to dyspnea and was supposed to be referable to the impermeability of the kidney. Uremic convulsions were seen in all cases and were probably due to cerebral disturbance. There was high blood pressure and the association of hypertension and the uremia was noticed. With complete rest the blood pressure dropped to normal, the edema disappeared and chlorides, which had been retained, were then excreted in large amounts. Albuminuria was at first increased with improvement and disappeared with recovery. This was due to the exudative function of the kidney. The cause was not determined, but the disease was supposed to be of infectious origin, probably trench fever. Two types were noted: (1) with slight rise of temperature and shin pains; (2) slight elevation of temperature and diminution of kidney function. By following up the patients for 18 months, it was found that the prognosis was good. Six cases went back to full line duty. There was no evidence that these cases developed chronic progressive nephritis. They seemed to be merely of an acute type, but it would be necessary to follow them up for several years to find out their development. The cardinal symptoms were: dyspnea, unrelated to acidosis; convulsions related to cerebral circulatory disturbance; chloride retention (urea retention was not noted usually); the cases usually cleared up under any simple form of treatment.

Dr. THOMAS MCCRAE of Philadelphia said that he had the opportunity to see many of these cases in a hospital in England. One sign appeared very striking, and that was the hematuria which persisted for weeks and months without any other sign, and in persons who were apparently well. In most cases there was no albuminuria. Dr. McCrae said he could not agree that the cases cleared up rapidly. It was a serious problem what to do with them. They lasted for many months. Many of them came in with uremia, or showed uremia in a very short time. Many patients shipped from France had convulsions on the way over and went into coma. This was probably due to cerebral edema. Many also showed hydrothorax. It would be very important to decide what the future of these cases would be.

Dr. GROAT said that he had under observation at the present time some men who were discharged from a French hospital and went back to their regiment.

Dr. L. F. BARKER of Baltimore asked Dr. Fitz why these cases were regarded as a different group. They did not differ from nephritis seen in civil life.

Dr. FITZ said he agreed with Dr. McCrae that these cases lasted for months, but nephritis in civil life practically lasted for ever. These cases tended to clear up at about 18 months. In regard to Dr. Barker's point he did not believe that in a civil hospital one found 5 per cent. of cases of acute nephritis. One was justified in calling this group of cases "war nephritis."

An Experimental Study of Cloth Impregnation with Pediculicidal Substances.—Drs. A. D. HIRSCHFELDER and W. MOORE of Minneapolis presented this paper, which was read by Dr. Hirschfelder. The study was begun in 1917 when Germans and cooties were a serious military problem. Under the auspices of the University of Minnesota and the National Research Council the whole question of the louse problem was investigated, covering the details of breeding, laundering, sachet powders, type of clothing to be worn, etc. This particular study was directed to the impregnation of clothing with some substance which would not only kill the lice, but last long enough to be effective through long periods when it was impossible to bathe or change clothing, and so protect from further infestation. The tests were made by keeping the lice in a glass-stopped vessel, with a strip of cloth impregnated with the substance tested, to see how long they survived. The feeding of the lice was done by Dr. Moore and his assistants. Exposure of the cloth to the air was done to reproduce actual conditions. The testing was done by Dr. Moore, the chemical preparations were made by the speaker. One year of work brought them to the point where British and French investigators had arrived previously. The great defect of cresol compounds hitherto used was that they evaporated in twenty-four hours. It was necessary to find a substance that would hold the cresol in the clothing ten or fifteen days. The most promising way seemed to be to introduce hallogens—oromine and iodine. Iodine was not found superior, however, to the original cresol, and chlorine was tried. Monochlorine was not any better. Dichlorine did not last more than forty-eight hours. Then bromine was introduced into the molecule and dibromocresol was used and increased the persistence of the substance five days. With dibromometacresol it lasted ten days. Different combinations were then tried, such as tribromocresol, but this had low volatility and did not evaporate quickly enough. Finally dichloromonobromometacresol was used, which was the best of all compounds and had a lasting power of thirteen days. Crude cresol was used, which was cheaper. Dr. Moore also prepared a salt of the tribromtricresol, which had louse-killing power after ten days, and upon exposure to the impregnated strip 80 to 100 per cent. of lice were killed in twenty-four hours. This substance was somewhat water-soluble and might be washed out by perspiration. It appeared, therefore, that the dibromometacresol and the dichloromonobromometacresol met the conditions best. The study was closed by the signing of the armistice. Future studies might be carried further.

Dr. HARRY PLOTZ of New York said that he would emphasize the importance of the louse problem in the army. Ninety per cent. of the troops in the front area were vermin infested. The problem was not at first appreciated in the United States. About 2 per cent. of recruits who came in were vermin infested; 42 per cent. of the negro troops were infested with body lice. Universal delousing should have been carried on before the troops went over. When the armistice was signed it was still a more serious problem because of the danger of bringing lice-borne diseases to the United States. Facilities for proper delousing were not available over there and it had to be carried out on a large scale on arrival of the troops in this country.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THIRTIETH ANNUAL REPORT OF THE STATE HOSPITAL COMMISSION. By C. W. PILGRIM, M.D., ANDREW D. MORGAN, FREDERICK A. HIGGINS, Commissioners. 446 pages. Illustrated. Published by J. B. Lyon Company, Albany, N. Y.

INDUSTRIAL NURSING. By FLORENCE SWIFT WRIGHT, R.N. 158 pages. Published by the Macmillan Company, New York.

A TEXTBOOK OF MATERIA MEDICA FOR NURSES. By A. L. MUIRHEAD, M.D. 177 pages. Illustrated. Published by C. V. Mosby Company, St. Louis, Mo.

DIE EXPERIMENTELLE BAKTERIOLOGIE UND DIE INFEKTIONSKRANKHEITEN, mit besonderer Berücksichtigung der Immunitätslehre. By Dr. W. KOLLE and Dr. H. HETSCH. Volume I. 660 pages. Illustrated. Published by Urban & Schwarzenberg, Vienna.

WAR NEUROSES AND SHELL SHOCK. By FREDERICK W. MOTT, M.D., LL.D., F.R.S., F.R.C.P., Brevet Lieut.-Col. R. A. M. C. (T.). 296 pages. Illustrated. Published by the Oxford University Press, American Branch, New York.

THE MEDICAL AND SURGICAL ASPECTS OF AVIATION. By H. GRAEME ANDERSON, M.B., Ch.B., F.R.C.S. 227 pages. Illustrated. Published by the Oxford University Press, American Branch, New York.

PSYCHOSES OF THE WAR. By H. C. MARR, Lieut.-Col. R. A. M. C. (Temp.). 272 pages. Illustrated. Published by the Oxford University Press, American Branch, New York.

ORGANOTHERAPY IN CERTAIN DISEASES AND CONDITIONS OF CHILDHOOD.*

BY E. BOSWORTH McCREADY, M.D.,

PITTSBURGH, PA.

IT is now some ten years since I first became particularly interested in the influence of the ductless glands upon normal development, their influence in numerous conditions of disease and abnormality when functionally or organically disordered, and last, but by no means least, in the results which might be expected from treatment directed toward the stimulation or modification of their activity. During this time I have had excellent opportunities for observation from the clinical side, and my own observations have permitted me, while fully appreciating the work done by physiologists, to realize that it took a clinician to clarify the scientific obscurities in which this subject has been veiled. To Sajous more than any other, I believe, belongs the credit for moulding the key which will prove the open sesame to a treasury of knowledge which will furnish the means through which the foundation of scientific medicine will become more stable, and treatment less of an art. Indeed, practical experience fully warrants the estimate passed upon him by a distinguished Pittsburgh clinician, Dr. John A. Lichty, last year when he said in the course of a discussion: "His clinical experience has been so well formulated and his observations so exact that he has anticipated by years very much of what has been established experimentally by laboratory methods."

We have witnessed the birth and death of many hypotheses of various kinds concerning the physiological action of the various hormones, suprarenal, thyroid, hypophyseal, thymic, pancreatic, hepatic, splenic, and what not—even the supposedly sound action of epinephrin on the blood-pressure. But Sajous's views, though differing from those of all others in the beginning, failed to die; they appeared on the scene over sixteen years ago and have stayed ever since, gaining strength every year. The reason for this becomes clear when we but gaze at the two portly volumes—the first book ever published on endocrinology, by the way—that contained his evidence. No man has ever studied from so many angles, so many coordinated data from all branches of medical science, a medical subject so obscure and so comprehensive. An edifice is built of many stones, he holds; sound deductions must be built o' many correlated solid facts. It is because of this doubtless that we clinicians find his deductions to meet our needs more satisfactorily than those of physiologists whose studies are restricted to a comparatively limited field.

We often hear of the difficulties of endocrinology, of the complexity of the subject. It is because of this unfortunate belief, due mainly to the contradictory experimental data published, that many practitioners deprive themselves of the great aid endocrinology affords in practice. Those of us who adopted as our main guides, after due study of those of others, the views that Sajous has published, have not only ceased to look upon the main endocrine organs with disconcerting diffidence, but instead with the same confidence we bestow upon the lungs as the organs of respiration, the stomach as an organ of digestion, the brain as the organ of mind, etc. Mentioning only the endocrine glands referred to in the clinical portion of this paper, I will summarize briefly the salient points of the functions that have met our clinical needs:

The *thyroid apparatus*, in which Sajous includes the parathyroids, he regards as carrying on two associated functions. The first of these is participation in general cellular metabolism in a most active manner. We know that it burns the body up, as it were, in Graves's disease, because it breaks down fats and, after them, other tissues. It also takes part in a function of capital interest to us practitioners, that which protects the body against infections and intoxications. The use of thyroid gland is therefore indicated where metabolism is slowed from any cause and to combat infectious processes.

The functions of the *adrenals*, the rock upon which physiological tenets met defeat (Prof. Vincent, a physiologist, having written recently, "We know nothing of the functions of the adrenal body regarded as an organ on its own account"), have always been interpreted differently by Sajous, even though he insists on the action of the adrenal secretion on the cardiovascular muscles. For him the adrenal secretion is the substance which takes up the oxygen from the air in the lungs, becomes part therein of the hemoglobin which carries oxygen to all tissue. That venous blood can be converted into arterial blood by adrenal extract has since been confirmed. To us clinicians this fact is of great value in practice. The effects of adrenalin in asthma, the terminal stage of infections, and many other disorders in which deficient oxidation and cardiovascular atony take part have abundantly shown the correctness of Sajous's theory.

He has always held that the *Pituitary body* was

*Read by invitation at the annual meeting of the American Therapeutic Society, June 6 and 7, 1919. For discussion see page 566.

not a secreting organ, notwithstanding the contrary belief held by practically everybody for a time, and presents many facts to the contrary. Prominent among these is that acromegaly is not always a general disease but is at times limited to one extremity or restricted area; also the utterly unreliable action of pituitary extracts in conditions clearly due to destructive disorders of the pituitary which it should relieve. Sajous has always held that the pituitary was a nervous organ containing sensory cells, whose principal rôle was to act as main coordinating center of the functions of the thyroid, adrenals, and kidneys—a view which clinical evidence tends clearly to sustain. The pituitary extracts do not represent a secretion at all, in his opinion, but owe their physiological action to adrenal substance in organic combination, as shown by the chromaffin and other tests. This explains their superior value to suprarenal preparations in many morbid conditions in which the latter are used, their action on muscular elements, vascular, uterine, intestinal, etc., and even the terminal cardiac depression of acute infections.

The *thymus*, to those of us who have much to do with the disorders of adolescence, is a most important organ. Here again, we find Sajous's view that the organ is not a secreting one, the most satisfactory in practice. He concludes that the thymus produces lymphocytes, which he termed "thymocytes," whose mission is to supply to the brain, the nervous system, and the bones, the extra nucleins they need during the child's growth. What this means to us when the development of a child, both nervous and osseous, is defective is self evident. Particularly does it become so when we recall that it is mainly through efficient activity of the thyroid and thymus that calcium metabolism is insured.

Sajous believes that the *testes* do not produce a true internal secretion, but that they restore to the blood substances which they borrow therefrom to build up, with the product of their adrenal rests, their autonomous secretion. All these substances contribute also to the formation, in appropriate structures, of semen—both fluid and spermatozoa, the latter, as is well known, being rich in nucleins. The substances returned to the body at large include, therefore, besides what portion of the autonomous internal secretion the organs of the genital system have not utilized, the usual reserve of materials created to good account, particularly during the period of growth, the presexual period of life.

In regard to the *ovaries*, Sajous believes we are not dealing with a true internal secretion as regards a fixed function in the organism at large. So far as available evidence permits us to judge, the ovary produces a secretion which sustains metabolism and nutrition of the sexual apparatus, of which the ovaries, the secreting organs, themselves form a part, and also of the menstrual function. During the intervals—only from his viewpoint as he wishes understood—the unused excess is absorbed into the general circulation, not as a special secretion or hormone, but as a part of the general asset in adrenal and thyroid secretions, nucleins, etc., with which the functions of the general organism are usually carried on.

The above briefly summarizes the known functions of the main endocrine glands as understood by Sajous and accepted by those who recognize his position as an authority on the subject. Those who dissent from his conclusions have yet to prove the reliability of their arguments. There are, however certain generalities upon which all investigators who have given the subject of endocrinology serious attention are agreed. As Leonard Williams says, "We know that metabolism is under the direct control of the internal secretory glands. We know that these glands preside over growth and development in infancy and childhood, that they are essential to mental, physical, and reproductive efficiency in adult life, and that they are responsible for the maintenance of catabolic balance in the period of decline. It is therefore no exaggeration to define the constitution of an individual as the resultant of his internal secretions."

Acceptance of the above theories concerning the functions of glandular activity opens up a wide field in the application of therapeutic measures whose purpose is the stimulation of glandular activity when and where it is deficient, its sedation where such activity is excessive, and the institution of proper harmony where imbalance of action exists.

The classical experiment of Brown-Séquard suggested a therapeutic application from which much may be expected. In fact, the administration of the various gland substances has become a valuable and, one might say, indispensable part of the armamentarium of the modern scientific physician, and will become even more important as knowledge becomes more extensive. It must not, however, be supposed that the endocrinologist is a blind advocate of indiscriminate organotherapy. In many glandular disorders glandular therapy has no place or at most a subsidiary one, the proper therapeutic measure being physical, hygienic, dietetic, medical, or surgical, or a judicious combination of some or all of these.

It is not my purpose to discuss in this paper the bizarre conditions of endocrine abnormality, as cretinism, dystrophia adipososexualis, infantilism, the precocious development due to malignant hypernephroma of the adrenals or to disorder of the pituitary body, etc. The incidence of these conditions is relatively infrequent, and I prefer to occupy the limited time allotted me to the consideration of conditions met with in the daily practice of practically every medical man.

The physical examination of a large proportion of our male population for army service, investigations into the physical condition of school children, and the baby caring campaign inaugurated through official and unofficial agencies, have served to show a prevalence of physical inferiority in modern life which to many is appalling in its extent. This inferiority is due to a multiplicity of causes acting singly, or, more usually, in combination, which may be grouped under the general terms of hereditary and environmental. Whatever the essential and underlying causes, there are few cases of organic inferiority in which the ductless glandular system escapes involvement in some degree. In some the functions of one gland, as the adrenals or the thyroid, control the clinical picture, and in these the therapy is naturally directed toward these particu-

lar glands. In others, the more typical cases of *congenital asthenia universalis*, the whole glandular system is hypofunctioning, and it is in these that pluriglandular therapy is most efficacious. Dupuy several years ago was so convinced of the advantage to be derived from such treatment that he suggested that the government (of France) should undertake to furnish the glandular preparations that the strength and vigor of the nation should be conserved. The so-called "delicate child" will often quickly respond to a combination of small doses of thyroid, pituitary, thymus, and the gonads. Overweight with flabbiness and mental sluggishness call for a judicious increase of the thyroid; low blood-pressure for additional pituitary or adrenal gland; slow growth with fragile bones and dental abnormalities for thymus, etc.

Much has been written regarding the use of the glandular products in feeblemindedness. In the treatment of this symptom-complex, the organic substances undoubtedly have an important place. But it is unlikely that, with the possible exception of cases due to true myxedema, a single case of feeblemindedness has ever been cured by organotherapy; improved—yes, and sometimes to marked extent. There is, however, a class of cases too young or too indefinite in type for a diagnosis of feeblemindedness to be made; children of tender years whose mental development does not at all correspond with what it should be at their age of two, or three, or four, who perhaps do not talk or walk, or who fail to present other phenomena common to their age but who develop along normal lines after a few months' administration of ductless glandular substances. The awakening of the mental faculties in some of these cases following a course of glandular treatment is sometimes most gratifying and too abrupt to be mere coincidence.

Where definite stigmata are present, as of microcephaly or mongolism, we know, of course, that the benefits to be derived from glandular therapy are only those of stimulated metabolism and nutrition, leading to an advance in development but never to normality. In hydrocephalus I have found small doses of thyroid of decided benefit, especially when mercury is given in the form of the corrosive chloride. In cases with defective physical development thymus and pituitary should be added. In epilepsy, particularly attacks of the petit mal type in young children, thyroid may be exhibited with the frequent result that the attacks will diminish in frequency and intensity and sometimes disappear entirely. In the troublesome polydipsia and polyuria designated as diabetes insipidus pituitary may give prompt relief. Some cases of enuresis in the spasmophiliac type will quickly respond to small doses of thyroid. Hemophilia and rickets are conditions in which thyroid and thymus may be used with advantage. Many of the skin disorders to which children are subject, as eczema and psoriasis, are benefited by the addition of thyroid to the treatment. In the treatment of congenital syphilis the addition of a pluriglandular combination or a small amount of thyroid will ensure results with smaller quantities of mercury or arsenic and maintain the patient in a better state of nutrition.

The physical and mental instability common to the onset of puberty, especially in girls, may be controlled by small doses of thyroid and the gonads. Enlargement of the thyroid gland at puberty is by many considered a physiological phenomena, but I believe that any distinct enlargement is an indication of improper functioning, not necessarily dangerous, but still requiring attention. Such enlargement does not occur in properly organized individuals, and is due either to inherent instability of the thyroid gland or to the unusual load placed upon it as a result of lack of equilibrium in the ductless glandular system as a whole. In either case proper hygienic measures of rest, diet, fresh air, etc., may tide the individual over this critical period. In others, more active treatment is indicated, and, paradoxical as it may seem, thyroid gland itself is useful in many cases. In others, ovarian and mammary substances or thymus give the desired results in stabilizing the correlative action of the ductless glandular system as a whole. Where extreme vagotonic excitability is present glandular treatment should be administered with great caution and is best combined with atropine or other drugs having a sedative influence upon such hyperexcitability.

Chlorosis is another condition peculiar to adolescence in which the ductless glandular system is intimately concerned and in which the classical treatment with iron is best preceded by a course of thyroid substance to stimulate the depressed functional activity of the adrenal system, which is an important etiological factor in this disease.

Organically inferior girls are peculiarly liable during the adolescent period to menstrual disturbances which are amenable to organotherapy, especially when combined with proper hygienic measures. Delayed and painful menstruation are common both in hyperenergetic hypoplastic individuals of neuter type, whose secondary sexual characteristics are indefinite, and also in the fat overgrown asthenic type. In the first the implication is pluriglandular with the gonads particularly at fault, and, while in the second class all the glands are more or less involved, it is the thyroid gland and pituitary body which particularly require stimulation.

We must not, as physicians, fail to realize that prevention is one of the most important functions of modern medicine. Many of the conditions which make for inefficiency of the individual in adult life are manifestations of a localized or general organic inferiority which inferiority may be removed or at least modified by proper treatment undertaken sufficiently early. The investigations of numerous observers have shown that we have in the organic preparations powerful adjuvants, if properly used, to treatment directed toward the stimulation of correlative growth.

I do not advocate the haphazard administration of organic substances. These are powerful agents and if improperly used are liable to effect more harm than good. Each case must be individually studied and treatment must be based upon a careful analysis of the symptoms; administering only that particular substance or combination of substances which is apparently indicated. The present tendency seems to be "when in doubt give thyroid," and as a consequence thyroid is, possibly, one of the most abused drugs we possess. If thyroid is given when what we really need, instead of a stimu-

lant, is a depressant to the functional activity of the adrenal center, as arsenic, the results are bound to be unsatisfactory.

Another cause for failure is improper dosage. Often five grains of thyroid extract is given when one-one-hundredth to one-fifth grain of the gland substance is all that is required. There is possibly no medicinal substance subject to so many apparent vagaries of action as thyroid. With most drugs some degree of tolerance may be established, but thyroid stimulates both structural and functional activity in the whole glandular system and for this reason symptoms of hyperthyroidism may suddenly occur in cases in which moderate doses have been borne with impunity for a long time. This, too, is to an extent true of other organic preparations and for this reason the beginning dose should always be small, and during the gradual increase the patient should be under the frequent observation of the physician. It is wise when possible to have a morning and evening charting of the temperature and pulse-rate. At frequent intervals treatment should be discontinued for a week or more.

Conclusions: 1. The endocrine glands control metabolism and preside over growth and development in infancy and childhood; they are essential to mental, physical, and reproductive efficiency in adult life, and they maintain catabolic balance in the period of decline.

2. Many diseases and conditions of childhood are manifestations of organic inferiority in the etiology of which dysfunction of the endocrine glands is a more or less prominent and contributing factor.

3. Treatment directed toward the stimulation, modification, or correlation of action of the endocrine glands is a promising field of therapeutic endeavor.

4. Treatment by organotherapeutic preparation should be preceded by a careful analysis and evaluation of the symptoms of endocrinous dysfunction.

5. The usual doses of organic preparations, particularly thyroid, are too large, are administered without due care, often in unsuitable cases, and tend to discredit a valuable therapeutic measure.

KEENAN BUILDING.

THE PRESENT ASPECTS OF ENDOCRINOLOGY.*

BY A. W. LESCOHIER, M.D.,

DETROIT, MICHIGAN.

RESEARCH LABORATORY, PARKE, DAVIS & CO.,

THE therapeutics of endocrine glands constitutes a phase of medical practice which has distinctly suffered from a lack of correlated laboratory and clinical study. The scientific side of endocrinology, as reflected by the results of physiological and pathological investigation, has to a large extent been divorced from the application of glandular extracts on a therapeutic basis. Experimental study has established the relationship of various members of the endocrine group to both normal and pathological physiology, so that it is now possible to interpret definitely important symptom complexes in terms of internal secretory disorders. Unfortunately, however, the therapeutic aspects of the subject have not been guided by the same scrutinizing consideration. Empiricism, rather than scientific study, has been the outstanding factor in the use of ductless glands in treatment, and this sort of therapy, from being one of the most delicate phases of medical treatment, has often assumed the earmarks of a patent-medicine "cure-all."

This situation has resulted in the development of two abnormal viewpoints on the part of medical men toward the therapeutic application of glandular products. On the one hand we have the not insignificant proportion of medical practitioners ready to feed on the latest rumor or fad, whose soaring imagination has been quick to embrace every wild hypothesis advanced in connection with glandular treatment, and to convert immediately dubious conjectures into established facts. In contradistinction to this class we have the other extreme of bald scepticism, a natural result of the reaction on the part of the conservative element to the faddist enthusiasm. The last-mentioned viewpoint frankly questions the value of glandular therapeutics except in a few clear-cut applications such as the thyroid in cretinism, and the employment of suprarenal and pituitary derivatives on a drug basis.

While deprecating the extravagant ideas of the unbalanced enthusiast, it must be conceded, on the other hand, that there is an unwarranted tincture of pessimism in certain of the criticisms which have been leveled at glandular therapy. There are positive as well as negative facts to be remembered, and the real usefulness of our knowledge of the internal secreting glands is largely to be measured by the degree in which it can be utilized in treatment.

The crying need of endocrinology at present is carefully controlled therapeutic investigation. While there is a great deal still to be learned about the physiology and pathology of these diseases there is no dearth of investigation in this direction; indeed, as has previously been suggested, the scientific study of the ductless glands has been dominated by the laboratory investigator, and such carefully controlled study as has been devoted to the clinical side of this question has been almost entirely focused on the striking and unusual types of secretory aberration, which, after all, are probably the least important in looking at the therapeutics of these disorders from a broad viewpoint. The relation of endocrine glands to such conditions as Graves' disease and acromegaly is interesting, but offers very little in the way of practical therapeutics. On the other hand, it seems probable that in the less distinct, the commonly unrecognized functional deficiencies, lies an important field of glandular therapy. The physician who is trained to recognize the less marked endocrine aberrations is the exception and not the rule. By way of illustration it may be pointed out that the diagnosis of cretinism and myxedema is not difficult, and the results from thyroid treatment in their control are definite and generally accepted. The physician does not, however, meet with cases of this type with any great frequency, while on the other hand the milder types of hypothyroidism are by no means uncommon.

The physician who has been taught to recognize

*Read at the twentieth annual meeting of the American Therapeutic Society at Atlantic City, June 6 and 7, 1919. For discussion see page 566.

the thyroid deficiencies will find this factor associated in many of the clinical conditions which he is called upon to treat. It may be found as a complicating factor in various nervous conditions, in menstrual disturbances, in anemia, chlorosis, and as a secondary factor in various chronic diseases. Thyroid insufficiency in pregnancy is quite a common occurrence. Cases of obesity exhibiting physical and mental sluggishness and an inability to maintain mental concentration, especially if associated with a dry, cold skin, may be attributed to hypothyroidism. Fatigue from slight exertion in individuals exhibiting good muscular development may be an evidence of thyroid insufficiency. These less distinct types of hypofunction constitute a much larger field for glandular therapeutics than the well-known thyroid syndromes, although the application of such treatment is not, of course, so vitally important.

Certain disturbances of the female generative system attributable to endocrine secretory aberrations constitute another group of general interest. With the exception of thyroid therapeutics there is, perhaps, no other phase of endocrinology in which the relationships are more definitely expressed and the opportunities for treatment more clearly indicated. The influence of ovarian activity on the menstrual function has long been recognized, and finds expression in many ways. More recently we have come to know that other glands, especially the thyroid, the pituitary, and the mammary, may affect the development or influence the functional activities of the sex organs.

It is not the purpose of this paper to review the physiology of or to discuss the interrelationships between these various glandular components, but merely to emphasize a few facts important from a therapeutic standpoint. Obviously, the rational field for glandular treatment includes those cases which are correlated with secretory deficiency.

The best-known application of ovarian treatment is the use of this gland in its entirety, or more often a preparation of the corpora lutea, in controlling the disturbances incident to either natural or artificial menopause. The results of glandular treatment in these conditions are not as consistent as we might naturally expect in view of the certainty that many of the symptoms, at least, are attributable to the disappearance of ovarian secretion. The failure in some of these cases is undoubtedly to be attributed to the complicating glandular factors; in other words, the disturbances of the menopause, whether occurring physiologically or as the result of removal or destruction of the ovaries, are to be interpreted as a general disturbance of the endocrine balance, in which the dominating factor is subject to variation.

The results of ovarian treatment are undoubtedly more consistent in certain disorders of the menstrual function. In so far as menstruation depends upon ovarian activity, we might expect that absence or scantiness of the menses would be associated with secretory deficiency, and conversely, that excessive or difficult menstruation would be the expression of hyperfunction. This is to a considerable extent substantiated by clinical experience, but other factors may be involved, especially in menorrhagia or dysmenorrhea, conditions in which the secretory element is perhaps less important than certain other factors.

The relation of ovarian activity is more frequent and positive in the disorders of the deficiency type; that is, amenorrhea or scanty and infrequent menses. This group of cases includes women who are physically underdeveloped, and whose menses, from puberty, have been irregular or scant; those in whom the menstrual function has been normal but subsequently becomes irregular or deficient, and who perhaps for long periods of time do not menstruate at all; and cases of amenorrhea or scanty menstruation associated with hysterical temperament. In these last cases the prognosis of glandular therapy depends upon whether the hysterical condition is referrable to glandular hyposecretion, or to an inherent instability of the nervous system. It is not to be expected that organotherapy will be successful in controlling disturbances in cases in which an inferior nervous make-up is the dominating factor. On the other hand, there is no doubt but that very profound nervous disturbances, and occasionally psychoses, may result from ovarian insufficiency during the active sex period of life.

A fact which is to be considered in the endocrine treatment of these patients is the possible necessity of utilizing some other preparation to supplement ovarian treatment. This applies especially to the pituitary and thyroid glands. There is a growing recognition of the importance of the pituitary function in its relation to gynecological conditions. Absence or scantiness of the menses, accompanied by a rapid increase in weight, polyuria, and marked carbohydrate tolerance, points strongly to a pituitary insufficiency. Undoubtedly the unsatisfactory results sometimes experienced in the glandular treatment of these cases are attributable to the failure of the physician to recognize these intercurrent factors. The intelligent application of glandular treatment depends upon the ability to interpret the cardinal symptoms of the important glandular aberrations.

A number of clinical reports have been made from time to time with regard to the use of ovarian preparations in the treatment of dysmenorrhea. It is difficult to understand why such therapy should prove beneficial. Undoubtedly the majority of cases of dysmenorrhea are attributable to anatomical lesions or defects of the uterus or its adnexa. Faulty development of the internal genitalia accounts for a considerable percentage. However, looking at the question from a standpoint of glandular function, we would naturally expect a hyperfunction of the ovaries rather than the converse; in which event, ovarian treatment would be distinctly contraindicated. On the other hand, it has been suggested that in some cases dysmenorrhea is due to a hypersensitive nervous system, and that ovarian deficiency predisposes to such a condition. Some favorable clinical reports have been submitted to support this idea. It must be conceded, however, that the efficacy of ovarian treatment in dysmenorrhea has not been well substantiated, and that the usefulness of such treatment is to be largely limited to the early puberal period as an agent to promote the development of the internal genitalia.

Menorrhagia, in the majority of cases, is undoubtedly attributable to organic conditions, but there

is a certain group associated with excessive ovarian activity. Here again ovarian or corpora lutea treatment would be distinctly contraindicated. It is rather an interesting fact that mammary preparations appear to be useful in these conditions. That the mammary secretes a substance which has a neutralizing effect on the ovarian secretion is fairly well substantiated. The abatement of the menses during gestation and the rarity of impregnation during the period of lactation are illustrations of the relation existing between these two glands. The therapeutic side of the question has not been exhaustively studied, but such clinical evidence as is available indicates that the mammary exerts a definite effect in neutralizing ovarian hypersecretion.

These passing references to a few practical applications of glandular treatment, not universally understood, are merely illustrative. Endocrine therapy does offer the therapeutic possibilities of undoubted importance. Its real usefulness will not be realized, nor its limitations appreciated, until medical men have abandoned the "cut-and-try method," and apply such treatment, guided by intelligent interpretation of the various glandular syndromes.

MEDICAL TREATMENT OF GOITER.*

By GRANVILLE RYAN, M.D.

Des Moines, Iowa.

In the medical treatment of diseases of the thyroid gland, we encounter some problems in the etiology, pathological anatomy, symptom complex, and medical therapy the solution of which is yet to be found in the domain of the experimental laboratories, which in turn must receive the endorsement and confirmation of the clinician in the practical test.

It is not our purpose to enter into a discussion of the theories from the standpoint of the laboratory technician or the research worker but merely to present some well-known facts and cite a few clinical observations which we have noted in our experience with these most interesting patients.

Considered clinically, we look upon abnormalities of the thyroid as being either (1) hyperplastic or (2) nonhyperplastic; and, irrespective of which of these groups the case is classified in, we ascertain whether or not it is (*a*) a toxic goiter or (*b*) a nontoxic goiter.

We will omit the details of etiology at this time except to state in a general way that, while many of the causative factors are known, one should individualize each case coming under his observation, and in our search for the cause of the abnormal inhibition or stimulation and activation we should consider well the personal equation in each individual affected.

Pathologically considered, the classification of Wilson is quite satisfactory. He asserts that pathological enlargements of the thyroid, aside from those due to acute and chronic infections by known organisms such as pyogenic cocci, tubercle bacilli, and *Spirochæta pallida*, may be considered as of four groups, viz., (1) Nonsymptomatic or simple goiters, (2) Toxic, nonexophthalmic goiters, (3) Exophthalmic goiters, and (4) Tumors of the thyroid.

From a clinical standpoint, a broad general classification is (1) Hyperthyroidism, (2) Hypothyroidism; and in making a diagnosis, first of all, comes the necessity for ascertaining whether we are dealing with a thyroid that is oversecreting, *i.e.* working overtime, or whether its production is below par, that is, not working hard enough; and, finally, whether instead of having an abnormality in secretory function we are dealing with pressure symptoms or just an unsightly tumor. In our effort to secure a correct understanding of the case we should keep in mind constantly the relationship existing between the thyroid and all the other glands of internal secretion which are so interdependent.

Goiter is to be differentiated from the neuroses, from lues, tuberculosis, cardiovascular lesions, the nephritides, tumors, infections, etc., by a careful history as to age, onset, habits, environment, occupation, etc., and a painstaking physical and laboratory examination is necessary to ascertain the functionating capacity of the body as nearly as possible. In this connection Du Bois' recent contribution relative to the importance of "the basal metabolism as a guide in the diagnosis and treatment of thyroid disease" is most interesting.

We know that in toxic goiter we see vasomotor disturbances of the skin and also that we have an increased metabolism. Therefore it appears that a quantitative determination of the heat calories produced is most helpful in ascertaining the degree to which the body functions are being overstimulated or understimulated, as the case may be. As stated by Du Bois, it is comparatively easy to diagnose Graves' disease when presenting the cardinal symptoms of exophthalmos, tremor, and rapid pulse, and a typical case of cretinism should not prove very difficult. But it is the atypical cases between these extremes which call forth our best efforts along diagnostic and therapeutic lines.

Hypothyroidism is usually manifested by a retarded development physically, and, to a greater extent, in the mental condition of the patient. This suspicion being aroused, a confirmative therapeutic test is given in the form of extract of the thyroid alone or in conjunction with extracts of one or more glands of internal secretion. Kendall has succeeded in isolating the active principle of the thyroid to which he has given the name of thyroxin. This is a most valuable contribution to our knowledge of this gland, for by the administration of thyroxin experimentally, he has been able to produce typical cases of Graves' disease, even to the point of carrying the animal *ad extremas*. Conversely, thyroxin has proven of inestimable value in the treatment of hypothyroidism by supplying the deficit to the comparatively inactive gland of the cretin.

It is particularly interesting to know that this thyroxin is stored up in the thyroid gland in summer and set free during the winter. Therefore it is easy to understand that metabolism is much more active in winter than in summer. Thyroxin acts as a catalytic agent in stimulating not only the organs of internal secretion but also in stimulating the cells of the body in general. Its action is more effective in the presence of iodine. Kendall has also been

*Read at the twentieth annual meeting of the American Therapeutic Society, in Atlantic City, June 6 and 7, 1919. For discussion see page 566.

able to produce thyroxin synthetically, and this fact promises ultimately to place the treatment of hypothyroidism upon a solid foundation.

In acute hyperthyroidism tachycardia is the initial symptom, as a rule, and is perceived by the patient as a rapid, pounding sensation of the heart, and soon becomes so uncomfortable that a sense of fear is precipitated and the patient makes the first call upon the family doctor. Here is where the doctor should appreciate and fully realize the responsibility thrust upon him, for the end results of treatment and the mortality are very largely influenced through his analysis and conception.

It is at this time that the individual affected should be given to understand that team work is imperative and that the end result will depend very largely upon the intelligent cooperation of the patient. Upon examination we find the pulse rate greatly accelerated, ranging from 130 to even 200 beats per minute. The heart is noticeably influenced even after being placed at absolute rest, by worry, fear, visitors, whether friends or relatives, or the examination of the attending physician. Frequently there will be a marked acceleration without any apparent cause. This rapid heart is, as a rule, regular, but will not stand for the continued insults of this toxic agent upon the myocardium, indefinitely. But very early we must expect degeneration, dilatation and arrhythmia, which may vary from an intermittence to even an auricular fibrillation.

Babcock observed some years ago how very persistent and intractable was this thyrotoxic tachycardia and that the persistent application of the commonly used therapeutic agents tended to aggravate rather than ameliorate the symptoms.

The condition of the cardiovascular system will depend largely upon the virulence of the toxin present. The enlargement of the heart and the murmurs are due to the damage done by this agent, if the lesions were not produced by a preceding endocarditis.

Plummer states that "the vasomotor disturbances, flushing of the skin, a sense of increased warmth, and perspiration, generally antedate tachycardia, while myocardial incompetence due to dilatation develops later." He has observed that the blood pressure is noticeably affected even in simple goiter, and that "it is the result from the discharge into the system of small doses of thyroid toxin over a long term of years." He has observed that it is the systolic pressure that is noticeably affected and consequently there is an increase in the pulse pressure. Babcock has observed that the rise in maximal pressure appears to show up more plainly as age advances, which would suggest that the thyroid secretion merely intensifies the tendency to arterial hypertension incident to advancing age, while Plummer believes the rise in pressure corresponds in degree to the length of time during which slight thyroid intoxication has existed.

"That true valvulitis should be present in some cases displaying signs of Graves' disease is not strange in the light of Rosenow's bacteriological studies of the thyroid gland" (Babcock). In twenty-five out of thirty-two glands operated upon at the Mayo clinic, he identified an anerobic Gram-positive diplobacillus-like organism, and isolated it from the blood on two occasions in a severe case of exophthalmic goitre and in conjunction with Dr. Moon in eight of twelve dogs having goitre.

Diagnostic symptoms of heperthyroidism according to their frequency and severity occur somewhat regularly in the following order: Cerebral stimulation, vasomotor disturbance of the skin, tremors, mental irritability, tachycardia, loss of weight, cardiac insufficiency, exophthalmia, diarrhea, vomiting, mental depression, and finally death.

As we see many of these cases after they have existed for some length of time, we find that there are secondary changes that have taken place as a result of the continued toxemia, such as myocardial degeneration, weakness and flabby condition of the muscles of the extremities, malnutrition, and disturbances of the nervous system in patients who are mentally depressed, hysterical, and abnormally sensitive to shock or emotional excitement.

In formulating treatment the condition just referred to, as well as many other possible complications, must be reckoned with in the manner indicated.

The entire pharmacopeia of medicine has been searched in the hope of obtaining a specific drug to convert the toxic thyroid into a normally functioning gland, but as yet the efforts have been unsuccessful for the reason that we have not alone the hyperthyroidism to combat, but there is an overstimulation of all the ductless glands resulting in a marked disturbance of metabolism in general.

Quinine hydrobromide is probably the most widely used drug, while antileutic treatment is often effective; the salicylates claim their quota, as do many other therapeutic agents in selected cases. Babcock states that "the treatment of tachycardia is very intractable to the drugs usually relied on to slow heart action and lessen dilatation. In some cases, in fact, digitalis seems to aggravate the patient's sense of palpitation. Absolute physical and mental repose accomplish more oftentimes than do medicaments, and yet tincture of aconite in full doses, 20 to 30 minims of the official 10 per cent. tincture, three or even four times a day, may accomplish something toward moderating the tachycardia and uncomfortable sense of pounding." We have found sodiumsulphanilate most effective in controlling the rapid heart, but it must be administered carefully under daily observation. We believe that environment, hygienic conditions, with absolute rest, physically and mentally, with the application of the ice bag to the gland and over the precordium, with perhaps the addition of small doses of bromides or phenazone to control undue nervousness, to be a good treatment for the acute exacerbations in hyperthyroidism, and that these measures augmented by the intelligent attendance of a well-trained nurse in a well-regulated institution provides the most efficient preoperative treatment. It has been our experience that home care or treatment of these patients is quite impossible, at least until one has the situation quite well in hand.

Porter's method of injecting boiling water into the gland substance to lessen the oversecretion is commendable where less heroic measures fail. Measured doses of the *x*-ray, as well as the removal of the tonsils or bad teeth, gives splendid results in selected cases. There remain those cases, however,

which require the combined efforts of the internist and surgeon and tax their abilities to the utmost to bring about the desired result. If degenerative changes have occurred on account of the severity of the strain or long-continuous insults upon the vital organs, the case is medical, at least until the damage is repaired, if that be possible, and the case is surgically fit. Crile has truly said: "If it becomes necessary to break the force of the disease with the scalpel, the case is still medical and should be returned to the medical side of the unit for observation and care until the recovery is complete."

CURATIVE VERSUS SYMPTOMATIC TREATMENT OF EXOPHTHALMIC GOITER.*

By CHARLES E. de M. SAJOUS, M.D., LL.D., Sc.D.,

Philadelphia.

In a recently published monograph, which on the whole reflects the prevailing attitude concerning the medical treatment of exophthalmic goiter, the following lines occur: "So long as there is no specific medicine for Graves's disease, the little which can be used is based purely upon symptomatic indications." Such a statement leaves the medical man but one alternative: that of treating more or less blindly the various discomforts and external signs of the disease, leaving its fundamental cause and the patient's life to take care of themselves. As regards a "specific," the many facts published in recent years, showing that the malady may be the result of more than a single etiological factor, tend clearly to indicate that the hunt for such a cure-all cannot but continue sterile. The final outcome of such teachings is well exemplified by the tens of thousands of patients operated upon at the Mayo Clinic and elsewhere throughout the land on the plea that medical treatment proved futile. In truth, the wonder is that any case should ever escape the surgeon.

Available knowledge is sufficient to-day to enable us to place our conception of the disease on a basis less worthy of the gibes of a Molière or of the sterner rebuke of a Laennec and more in keeping with medicine as a science. It is this conception that I wish to lay before you to-day.

There have long been, as you well know, two main theories regarding exophthalmic goiter, (1) that it is due to excessive thyroid activity; (2) that it is a nervous disorder. Time has shown, however, that, as is often the case with strong and well-sustained hypotheses, both were correct and more or less interwoven. Moreover, other ductless glands have been found to participate in the morbid process, the adrenals and thymus in particular. These fundamental facts being no longer disputed, we are brought to inquire into the cause of these morbid phenomena. Why is the thyroid gland overactive and in some cases enlarged? Why is the nervous system so deeply involved in the process? Why are all body structures the seat of destructive erethism?

We now know that various toxics or toxins originating from the intestines, pyogenic disorders of the tonsils, nasal and the faucial cavities; peridental and gingival pyorrhea, gastroptosis with prolonged retention of ingesta, etc.—may underlie the morbid process. We know also that when these disorders are carefully sought and as thoroughly eradicated, all the symptoms due to hyperthyroidism improve and often disappear. These various sources of general intoxication obviously constitute the fundamental factor of the disease and yet, most writers, particularly those who speak of "symptomatic" treatment, fail to refer to them. The reason is not far to seek: Some overlook the toxemia. Others, though admitting it, fail to take into account the one factor which elucidates the whole morbid process, viz., that it is in defending the body against intoxication that the thyroid body becomes abnormally active.

Those who have ignored this function, though recognizing the importance of a toxemia, usually fall back on a single line of experiments, that of Reid Hunt, who found that white mice were protected from acetonitril poisoning by thyroid feeding, the protection corresponding with the proportion of thyroid given, while rats and guinea-pigs became more susceptible to acetonitril poisoning when given thyroid. But this experiment is only remarkable in the sense that thyroid afforded any protection at all to the white mice, since acetonitril is toxic owing to the hydrocyanic acid it liberates. The rats and guinea-pigs, on the other hand, responded as would man to the poison, for as we shall see later, the catabolic action of thyroid, so well shown by its action on fats, tends also in large doses, to cause general vaso-dilation, precisely as does hydrocyanic acid. All it did, therefore, was to add to the toxicity of the latter. Need I state that many poisons such as the cyanides, the nitrites, the coal tars, the opiates, the bromides, the salicylates, for instance, do not evoke a defensive reaction of the thyroid because they depress certain functions whether cellular, vascular or central? Need I urge that we are dealing with no such toxic agents in the genesis of exophthalmic goiter, but with causal factors such as coprostasis, tonsillar, nasal, faucial, dental and other infections which are well known to provoke, when certain pathogenic organisms are present, a defensive reaction of a most active kind, and complications such as acute and chronic endocarditis, articular rheumatism, and other grave disorders?

Limiting this analysis then to its legitimate field, what are, briefly, the facts that point to the defensive function of the thyroid?

Summarized, the observations of many physiologists, pathologists and clinicians have clearly shown: (1) that removal of the thyroid apparatus reduces markedly the antitoxic and bactericidal properties of the blood, and that these properties are restored by giving thyroid gland; (2) that the blood and urine are rendered more toxic by removal of the thyroid apparatus, but that this unusual toxicity is removed by giving thyroid gland; (3) that animals are rendered more susceptible to infections by removal of their thyroid apparatus, but that they can be protected against certain toxins, particularly those capable of caus-

*Read at the twentieth annual meeting of the American Therapeutic Society, June 6, 1919. For discussion see page 566.

ing a febrile reaction, by giving thyroid gland. My own labors having indicated that this antitoxic action of the thyroid secretion was similar to that attributed by Sir Almroth E. Wright to opsonins, and also that it was a component of the systemic autotoxins or alexins, this was confirmed by several European experimenters, Fassin, Stepanoff and Marbé. Frugoni, Grixoni, and many other clinicians, including myself, have also conclusively found that thyroid medication promptly influenced favorably both autointoxications and infections.

Beebe,[1] even though he quotes the irrelevant Reid Hunt experiments in opposition to the antitoxic theory, ascribing the susceptibility to infections to "a thymico-lymphatic constitution"—an obscure factor, nevertheless recognizes that "the relation of thyroid disease to previous infections has been noted clinically by many observers" and states further, that "If the thyroid secretion is an important element in the defense against infections, it is not impossible that it is stimulated to overactivity when occasion demands, and if the stimulus be often repeated, it may produce changes which we recognize as pathological. Through the repeated stimulus to overactivity, the gland has become hypertrophied, and its heightened function continues long beyond the stimulus which called it forth."

Others have attributed the antitoxic power of the thyroid to the active metabolism it provokes. But this in no way weakens my view as Beebe defines it, "that the mechanism of the defense against infections depends to a degree on thyroid function." It only explains in another way the manner in which the defensive reaction is carried out. The truth of the matter, the details of which I cannot develop here, is that the defensive function is part and parcel of the metabolic process, since it is by subjecting toxins, bacteria, etc., to catabolism, precisely as it does in breaking down fats and albumins, that the thyroid secretion carries on its protective role. Indeed, Plummer[2] recently stated that "the thyroid hormone is fundamentally a part of the catabolic process of higher animal life."

There is another etiological factor which demands elucidation. As every clinician knows, many cases of exophthalmic goiter are due to terror or severe fright, particularly when associated with traumatism; also profound grief, violent excitement, rage, etc. There is no doubt that fright may alone cause the disease. In a case personally observed, the active symptoms of the disease began one week after the accident, the sudden fall of an elevator down eight stories without causing the previously-well male victim any physical injury, the elevator being supplied with a safety air-cushion. In another, the patient after an automobile accident entailing only great fright, suffered when almost well after treatment, a recurrence of all her symptoms, as the result of another, though less serious automobile accident. These and many instances during the war, the San Francisco earthquake and other disasters, illustrate the influence of severe mental stress of the kinds described. As Cannon[3] well states, "Any high degree of excitement in the central nervous system, whether felt as anger, terror, pain, anxiety, joy, grief or deep disgust, is likely to break over the threshold of the sympathetic division and disturb the functions of all the organs which that division innervates"—one of which I may add, is the thyroid. They entail also, in the light of Crile's work, a physical exhaustion of the cerebral nerve-cells, the cell-bodies of which show marked chromatolysis. We are evidently dealing, as we shall see presently, with a toxemia due to impaired metabolism in these cells giving rise to toxic wastes which provoke excessive thyroid activity.

Again, do we find biochemistry and clinical medicine working hand in hand to elucidate crucial features of a fundamental problem. Chromatolysis, often mentioned by Crile, denotes more or less disintegration of certain components of nerve cells, their chromatin. As far back as 1903 I held that nerve cells received blood plasma containing adrenal substance, converted in turn into oxyhemoglobin (adrenoxidase). I also traced the latter in the axis-cylinders (into which, as you well know, the toxin of tetanus, tetanotoxin, also gravitates) in the cell body, the neuro-fibrils, etc., of the neuron or nerve cell. Every link of this chain of events has since been sustained by the observations of others. Lichwitz has shown that adrenalin gravitated in nerves; Macallum, of Toronto, found that sympathetic nerves contained an adrenalin-like substance; and Menten, of Chicago, found that the adrenal product did become converted into oxyhemoglobin. On the whole, I held that the nerve cell lived and breathed, so to say, as do other body cells, but with adrenals and thyroid hormones taking part in the process.

Now, as regards the influence of excessive mental stress, fear, anger, etc., upon this process, Vas, Mann, Lambert, Lugaro, and others long ago showed that nerves fatigued by stimulation more or less rapidly lost this substance, quite in keeping with Crile's more recent clinical views, and with those of Cannon. Briefly, fright, anger, etc., bring about disintegration of the nerve cell, by subjecting it to violent stimulation, which means excessive metabolic activity. And it is here that the primary toxic or cause of exophthalmic goiter in these cases appears, e. g., excessive metabolism of the nerve cell is known to produce phosphoric acid, cholin, and also a substance known to be particularly poisonous, *neurin*, a body closely allied to muscarin, especially. So sensitive is the thyroid gland to the latter poison, in fact, that it was once believed that the one function of the organ was to destroy neurin as fast as formed. In the light of these facts, therefore, we again realize that a poison, though neurogenic this time, can become the primary cause of the disease.

But why, the excessive stress due to fear, rage, etc., once terminated and entirely appeased, does the morbid process continue? Why do all the morbid symptoms, particularly those of nervous origin, persist? This is due to a vicious circle. The thyroid, powerfully stimulated to react against the intoxication, itself becomes a destroyer of the nerve cell. This becomes intelligible when we recall that besides the chromatin, the nerve cell is likewise rich in fatty substances, lecithin

(containing stearic, palmitic or oleic acid) in particular. If we now recall the familiar fact that thyroid gland first attacks fats, breaking them down sooner than any other tissue, we can realize why it is that excessive thyroid activity so actively disturbs the nervous system. Briefly, *a severe mental stress*, fear, rage, deep grief, etc., *causes excessive catabolism in the nerve cells, and the excretion by them of highly toxic wastes, including neurin; these poisons by provoking a defensive reaction of the thyroid, cause it to break down fats, including the fatty components of the nerve-cells, thus establishing a vicious circle, by perpetuating the catabolism of these cells and the formation of poisons.*

This accounts for the severity of such cases, unless, as we shall see, they are treated, not symptomatically, but in such a way as to arrest the excessive thyroid activity. It accounts, moreover, for the well founded contention by many authorities, that exophthalmic goiter is a nervous disease. Our regretted fellow-member, Prof. Putnam, of Harvard, who passed away a few months ago, was convinced that this view was the only one that explained its symptom complex. The conception submitted in these pages indicates that he, as well as the advocates of the thyroid origin, were right, the actual morbid process in reality encompassing both conceptions.

This interpretation suggests that a toxic origin of any kind, intestinal, gastric, tonsillar, etc., should likewise entail destructive catabolism of the nerve-cells. The only difference between this etiological class and the neurogenic, reviewed above, is that in the neurogenic the sudden emotional stress or shock to which the nervous system is subjected at once starts the pathogenic catabolism in its cellular elements, while in the former, that due to toxins, the morbid process, both as regards the thyroid reaction and the pathogenic catabolism in the nerve cells, is started insidiously, the toxemia being at first successfully antagonized by the defensive process in which the thyroid takes part. Gradually, however, as the tidal wave of toxins rises, the thyroid activity assumes proportions which soon entail not only the breaking down of systemic fats but also of those constituting the ground substance of the nerve cells, thus involving the entire cerebrospinal and peripheral nervous systems.

Treatment need no longer remain within the precincts of empiricism under these conditions. Much less should it be symptomatic, since this often entails the use of drugs which, though affording relief, tend to perpetuate the disease, by adding, unless the remedies are carefully chosen, thyroid excitants, digitalis, strychnine, adrenalin, etc., to those which already provoke hyperthyroidism.

Beginning with the neurogenic form, our aim, in the light of the foregoing data, as soon as any sign of hyperthyroidism follows the emotional stress, is to insist on *absolute* rest. Its object is to limit general muscular metabolism to the strict minimum, thus reducing the muscular wastes formed, and also the labor of the cardiac muscle. Mental rest is at least as essential since cerebral activity, by imposing labor on the stressed cortical cells, adds cholin, neurin, phosphoric acid, etc., to these poisonous wastes already produced in excess. Absolute rest thus inhibits two most important channels of poisons which goad the thyroids to abnormal activity.

Another aggravating factor in such cases is the use of inappropriate foods, those rich in proteins. Thyroidectomized dogs suffer severely when fed on meat; they recover when fed on milk; carnivora in general suffer seriously, herbivora least from the same operation. Obviously, the thyroid must contribute to the breaking down of meat proteins. Indeed, while Falta found that proteins increase the activity of the thyroid, Rudinger observed that a diet free from proteins and rich in carbohydrates tended to the opposite. Our aim being to inhibit thyroid activity, we should, therefore, prohibit all meats, butcher, fowl, fish, oysters even, and feed the patient only on milk and its various products, butter, cheese, cream, buttermilk, vegetables, and ripe fruits, watching out for acidosis by testing the saliva with litmus, and using freely as beverage imported Vichy (Célestin) to neutralize with its sodium bicarbonate what phosphoric acid the blood may contain—another source of thyroid excitation but also to protect the kidneys.

Important in this connection is the fact that the intestines, owing to the nervous disturbance, may fail to carry on their functions, thus causing in these neurogenic cases a retention of fecal matter which itself may, through the production of toxins by colon bacillus colonies, provoke considerable thyroid reaction. A saline purgative, sodium sulphate preferably (not calomel which is another thyroid stimulant), followed up, if need be, with sodium phosphate, a teaspoonful in a glassful of hot water each morning to prevent constipation, will usually suffice to eliminate this fourth source of thyroid excitation.

A neurogenic case, treated soon after the emotional stress in this manner and without drugs, will usually respond satisfactorily, even though the tachycardia be marked—130 or more. The pulse steadily goes down to normal and when the vicious circle is broken, often stays there. But the fire is readily kindled anew. In one of my cases, a short dance, after the pulse had been 84 nearly two months, promptly caused it to jump to 130 and to stay there, thus imposing a resumption of the rest, dietetic measures, etc. This means that the thyroid remains hypersensitive for several months after such an experience and that adequate precautions are in order during that period.

Unfortunately, most cases do not reach the endocrinologist early. In most instances, the patient has run the gauntlet of various diagnoses, often neurasthenia or some undefined heart disease, and been given tonics, also digitalis, which do more harm than good, while the loss of weight, the hot skin, and sweating may have suggested internal cancer, tuberculosis, or even typhoid fever—conditions suggesting more or less medication that fits the erroneous diagnosis, though not the patient. When, however, enlargement of the thyroid, which occurs only in about one-fourth of all cases, becomes sufficiently marked to be clearly perceived, this sign plus the tachycardia prompt "symptomatic" treatment, which is persisted in a

long time. This failing, the surgeon is recommended. Another source of delay is thus inaugurated, the operative risk, the scar, the possible after-effects, etc., being as many deterring factors which finally, when it becomes a question of life or death, convert the case into a poor operative risk or one difficult to handle by the endocrinologist—meaning by this term, a general practitioner who knows enough of endocrinology to treat such cases intelligently.

By this time, the measures previously described, though quite as important, no longer suffice. Another source of toxemia has entered upon the scene, to aid the toxics previously mentioned in destroying the patient. This factor is an extension, so to say, of the excessive catabolic action of the thyroid hormones, when the protective activity of the organ becomes so aggressive that it begins to break down, besides the systemic fats, the albumins and various tissue cells of the body at large. When this occurs, the loss of weight of the patient is sometimes astounding—122 pounds in eleven weeks in a case of Schlessinger's; 47 pounds in a few days in one reported by Funke. Some patients literally wilt before one's eyes, though in the average case the emaciation is progressive. The increase of tissue wastes thus produced contribute further the goad the thyroid to inordinate activity.

All muscles, vascular, cardiac, intestinal, and skeletal, being subjected to this catabolic drain of thyrotoxic origin, a resulting symptom, besides the more or less rapid emaciation, is the familiar general vasodilatation. It involves arteries and veins, both large and small, and is so marked that it is distinctly visible and may readily be discerned wherever sought, including the eye fundus. Affecting as it does all vessels, it accounts for the diarrhea, the muscular fatigue, the low blood pressure, the weak cardiac diastole, the exophthalmos, the headache, the cutaneous heat, flushing, pruritus, and hyperidrosis. Although this represents quite a series to treat symptomatically, one line of remedies prevents them all, provided absolute rest, mental and physical, and the restricted diet, previously outlined, are insisted upon; these agents are the vasoconstrictors. Ergotin, first used by Huchard, and the salicylates, recommended by Babinsky, are the best of these. Forchheimer's use of ergotin with quinine hydrobromide was fully warranted, the quinine adding not only its vasoconstrictor effects to those of ergotin, but tending also by stimulating phagocytosis, to aid the defensive functions. Hence, its good effects in some cases. I prefer a combination including sodium salicylate, to favor, besides, hepatic antitoxis. The formula used is as follows:

℞

Ergotinæ .....3ss (2 Gm.)
Sodii salicylatis
Quininæ hydrobromidi āā.3iiss (10 Gm.)

M. et ft. capsulæ No. xxx

Sig.: Two capsules three times daily one hour after a meal.

Owing to the bromine ion in the quinine hydrobromide, the tinnitus aurium is practically prevented. In some instances, however, it persists; or again it is at times advisable to interrupt the use of ergotin; under these conditions its vasoconstrictor effect, particularly if there is headache, may be sustained by giving

℞

Acetphenetidini
Caffeinæ citratis āā.....gr. xx (1.3 Gm.)
Sodii bicarbonatis.....gr. x (0.65 Gm.)

M. et ft. capsulæ No. x

Sig.: Two four times a day at equal intervals.

The caffeine, by producing increased capacity for muscular work, also tends to slow the heart, and reduce the fatigue.

The main remedial role of vasoconstrictors in the process, however, is that they tend through their direct stimulation of the vasomotor center, to restore the vessels to their normal caliber, including the arteries of the thyroid. As a result, the volume of arterial blood admitted into the organ is reduced, thus restraining directly its functional activity. Cold water compresses, the ice-water bag, allowed by its weight to exert a slight continuous pressure upon the goiter, while the patient is in the recumbent position, tends further to promote vasoconstriction.

In some cases, it is necessary, furthermore, to inhibit directly the thyroid function besides. Arsenic, as shown by Mabille and confirmed by Ewald and many others, fulfills this rôle. Again, to promote recovery after the causative disorder has been removed, it is often necessary to build up the nerve cell. Lecithin, glycerophosphates, thymus gland owing to its nucleins, all of which contain phosphorus, then become our main sheet-anchors.

This represents the main lines of treatment usually employed in the *worst class of cases of exophthalmic goiter we are called upon to treat*—those due to violent emotional stress.

How do these therapeutic measures differ from those employed in cases due to some infection, tonsillar, dental, gingival, nasal, adenoids, aural, intestinal vaginal hepatic, etc.? Only in that the causative disorder, whatever it is must be radically removed. Thus, local treatment of diseased tonsils is useless; often the abscesses are deep seated beyond reach, the organs must be resected; diseased teeth found so by *x*-ray examination, must be extracted, etc. The absence of intestinal corprostasis should not be surmised but established by a barium meal and *x*-ray or fluroscopic examination. If present, high enemas, the patient lying on the right side, to enable the water to reach the cecum should be used. Half-way measures are futile because the gland persists secreting abnormally as long as the slightest toxemia lasts. Once this point attained, the rest, diet and remedies described above, persisted in until the tachycardia has totally ceased and fails to return under graduated exercise, bring on a lasting cure.

The dominant rôle attributed to the thyroid gland justifies measures such as hot water or quinine and urea injections into the gland; also the ligation of some of its arteries to limit its secretory areas. *X*-rays, advocated by many reliable men, tend in the same direction; radium likewise. The Rodgers and Beebe sera also have a place among

the resources, since they promote the destruction of toxins through which the thyroid is kept pathologically active. Thyroidectomy carried out on modern lines, breaks up the vicious circle by removing a sufficient portion of the secreting structures of the thyroid to arrest the destructive catabolism which the organ perpetuates.

Yet, why is it that all these measures, including surgery, fail to insure complete recovery in the majority of cases? The average physician thinks only of the operative mortality of Kocher, the Mayos and other equally efficient operators, which operative mortality has become virtually nil. But the *ultimate* results even in such hands tell a different story. Judd and Pemberton,[5] of the Mayo Clinic, for instance, give 45 per cent., as the proportion cured eight years after operation. Starck[6], reviewing the final results of several prominent German surgeons, places the cures at approximately 30 per cent. Unfortunately, while there are throughout the country other surgeons of first order, the majority cannot conscientiously be so graded. Operative mortality grows apace with deficiency of operative skill and knowledge and to place it at 6 per cent., and the ultimate results, say after four years, at 18 per cent. cures, is to be generous to the average surgeon.

Medical treatment must be considered in a different light to convey the truth. Frankly, the physician who, without specific knowledge of endocrinology, treats cases of Graves' disease "symptomatically" as he is taught in text-books, merely lubricates the patient's downward path; he smoothes it, but often hastens progress. Surgery, on the other hand, even in unskilled hands, by resecting a part of the gland, removes more or less efficiently—sometimes too much so—one of the links of the pathological chain. We can only compare with surgical measures, therefore, the results of men who have, with the aid of endocrinological knowledge and experience, so employed what empirical measures their armamentarium furnished, as materially to aid the patient. Again, we must not forget that while the surgeon selects his cases, the physician treats all—a fact which of course increases his statistical mortality. Even leaving out of question the figures of Leonard Williams, White, Forchheimer, Lichty, Bram and my own, which might seem to favor the medical side, we may regard Syllaba's[8] percentage based on 51 cases of fifteen years' standing, viz., 33.3 per cent. cured as the average result of the clinician. This percentage as compared with that of the surgeon's 30 per cent. warrants the general conclusion that insofar as ultimate results are concerned, they are virtually similar in the hands of men of corresponding ability in this special line of work.

Why then should only one-third of the cases be cured? The reasons, from my viewpoint, are, in the first place, that the primary cause of the disease, the source of intoxication, which goads the thyroid apparatus to excessive activity, is overlooked. After partial thyroidectomy, it means continued excitation of the portion of the organ left in situ, and in the majority, only "improvement," a condition far removed from "cure," judging from cases I have had to treat. If too much glandular tissue is removed, a condition worse than myxedema—again speaking of operated cases that have drifted my way—is the remote result. If the causative infection or autointoxication is carefully removed and treatment on the lines I have outlined—in which random medication has no place—is instituted, over fifty per cent. of the cases will not require operation. If, however, owing to pathological hypersensitiveness of the gland due to prolonged excitation, operation becomes necessary, the surgeon will then obtain not 30 per cent. of cures, but recovery in practically all uncomplicated cases—provided the primary toxic factor has actually been found and eliminated.

As to the clinician, I do not hesitate to state that he should no more treat a case of Graves' disease on "symptomatic" lines than he should treat an eye doomed to destruction on random measures calculated to afford relief. It is by seeking the primary cause and eradicating it that he also will cure his cases. This, however, is subject to the proviso that he will not neglect the collateral factors I have enumerated: absolute rest, a bland unexciting diet, careful avoidance of drugs that excite the thyroid, and the judicious use of remedies that will either directly or indirectly inhibit its functional activity. If, after removing the primary source of intoxication, the gland, after a reasonable time, is still causing trouble through structural changes or hypersensitiveness, then many excellent measures are at his disposal: arterial ligation; partial thyroidectomy; hot water or quinine and urea injections; *x*-ray or radium treatment, to finish the good work and do full justice to his patient.

The following *conclusions* are submitted:

1. The symptomatic treatment of exophthalmic goiter generally resorted to, compromises the chances of the patient's recovery by leaving unassailed the primary cause of the disease.

2. Many patients are subjected to thyroidectomy entailing risks and morbid after effects, who could be cured by medical treatment did the latter aim to remove the primary cause of the disease and its morbid effects.

3. The remote results of surgical treatment would be greatly improved were removal of the primary cause of the disease and its morbid effects first insured.

4. All cases of exophthalmic goiter are due primarily to some toxin originating from some pathological process in one or more organs, either the tonsils, sinuses, nose, nasopharynx, teeth or gums, stomach, intestines, genitourinary organs, the nervous system, etc.

5. Even the cases due to emotional stress have as their primary cause toxic wastes formed in the cerebrospinal neurons subjected to stress: cholin, phosphoric acid, and particularly neurin, a highly poisonous waste-product.

6. These poisons, by exciting the thyroid apparatus to supranormal activity, owing to the active part taken by this apparatus in the defensive functions, cause it to secrete excessively, thus producing an additional toxicosis.

7. The thyroid hormone, particularly when pro-

duced in excess, taking part also in tissue catabolism, breaks down fats, including the fatty bodies in nerve and brain cells, thus accounting for the striking nervous phenomena of the disease.

8. Exophthalmic goiter thus becomes the product of a vicious circle in which three toxics take part: the primary causative poison which excites the thyroid; the excess of thyroid hormone as second poison; the excess of catabolic wastes due to the thyroid hormone, as third poison.

9. Timely removal of the disorder which produces the primary causative poison, by arresting the excessive thyroid activity, will thus prevent the triple toxicosis, and cure the disease.

10. The after-treatment—some such as described above—must also aim to remove the effects of the poisons to insure cure, dropping the "symptomatic treatment" as an empiric method unworthy of modern science.

MEDICAL SOCIAL SERVICE IN REHABILITATION.

BY WILLIAM H. SHELDON, M.D.

NEW YORK.

THE development of the social service department in connection with the Clinic for Functional Reeducation at No. 5 Livingston Place, New York City, was the result of the necessity for some mental reeducation as well as the physical rehabilitation which was the direct purpose of our work at the clinic. The point of view of the returned soldier we soon discovered to be different to that of the average civilian. The younger men who enlisted in the army had gone to France with the firm conviction that they would surely give their lives for their country. Their outlook on life while in France was that of men who live only for the day. Before being wounded they had been subjected to painfully disagreeable surroundings, great physical danger, and every form of shock. Much of their leisure had been spent whiling away the time playing poker or craps, seizing any means of distraction to relieve the monotony of their existence. The men whom we are treating are therefore rather surprised to find themselves back in the United States, wounded, but very much alive and obliged to face again the ordinary problems of existence. The point of view they held in France, while entirely natural under war conditions, is hopelessly demoralizing to them, now that they are about to return to civil life. It seemed to me, confronted with this peculiar psychology, that their minds were in need of functional reeducation no less than their injured bodies, and that the great aim of our social service should be to aid the men by every possible means once more to take their places, and if possible better places, in the world of industry.

In organizing the social service with this end in view we found it necessary to coordinate under one head all the numerous activities in the hospital, other than the strictly medical or surgical, in order to avoid duplication of effort and to enable us to deal more intelligently with the individual man. All the work is grouped under various subdivisions. We have a division for amusement and entertainment. One of the most noticeable characteristics of the men has been their intense physical and mental restlessness; they are unable to sit down and read or concentrate on a severe subject. In the wards one finds the patients constantly changing their position and walking about. British physicians to whom I have talked, who have been engaged in similar work have confirmed this observation. Bearing in mind that the cause of the men's restlessness was to a certain extent due to monotony, we have endeavored to bring the men in touch with the various organizations which are providing amusement to wounded soldiers and we therefore list the activities of the various other organizations in the city, instruct the men as to the best method of getting in touch with these facilities, and advise each man individually as to the sort of amusement which is best for him. Not only do we bring the man in touch with these other organizations, but we have various entertainments of our own, in the form of musicales, etc. Incidentally, we find the most popular form of amusement to be dances and so great has been the demand for lessons in dancing that we have provided an instructor, who holds classes once a week at the Clinic. It has been quite surprising to us to learn the number of men who are anxious to dance but who had never had the opportunity to learn. At various times theater tickets are given to us which we distribute among the men and we not infrequently have had one or several boxes at the opera given us. We find that almost universally the men are bored by the more serious plays and the opera, there evidently being a great desire for the lighter type of play. At the present time men are getting up a minstrel show, which from the point of view of the interest in keeping them busy has been the most successful of our ventures. We find automobile rides the popular form of amusement, and they are very beneficial to men who are recently recovering from operations.

With regard to the dances it seems much more sensible that girls approximately of the men's own station in life should be their partners, as often the boys get totally false ideas from dancing and being associated with girls whose position is quite remote from theirs. Not long ago a boy who has refused all the educational advantages offered him by the Government was found at one of the clubs dancing and in conversation with one of our workers, told her that life held so many advantages here in New York that he did not intend to go to work until his money gave out, and then he certainly would never go back to Hicksville, now that he had learned what life was like in New York. Our point of view, of course, in all our amusements is to rest and help the boys so that they may become useful citizens once more,

and any influence which tends to spoil or give them false standards of life is greatly to be deplored.

We have a division of occupational therapy, and like other hospitals with soldier patients, we have been bravely struggling to interest the men in some one of the many kinds of work which have been advised. We have found the average American youth does not take kindly to basket making, leather work, or bead making. It takes a great deal of persuasion and interest on the part of some of our aids to get the men eve nto start such an occupation. For some reason the American seems to consider such occupation effeminate, while among our foreign patients the tendency is to take up such work with enthusiasm and resulting great benefit. Of the various forms of occupational therapy we have found typewriting to be the most popular. The average man seems to wish to learn how to run the typewriter and he attends the lessons regularly and spends much time practising between times. There has been an express desire in not a few of the men to have lessons also in bookkeeping, and we have arranged to give courses in that subject. Carpentry has not been very popular among our men, although occasionally a man works quite steadily at it. We feel that occupational therapy is a very important branch of our work and offers great possibilities for the correction of deformities in a more natural manner than is now accomplished by the instruments of mechanotherapy. However, as yet, while the individual man is benefited we cannot point with any great pride to our achievements in this line. We hope in the future to extend our work and eventually to have extensive workshops and study the various groups of muscles which are used in the different pursuits. This is a study, I believe, which has yet never been made, occupational therapy having always been studied from the standpoint of its psychic effects. We keep a certain number of our men busy in the workshops of the Red Cross Institute, who were so kind as to offer their facilities to any of our men, whether for a week or a month, in order to finish some definite course of study. We feel that this would be the most satisfactory solution to our problem with regard to occupational therapy, inasmuch as at the Red Cross Institute, a man learns a definite trade. Owing, however, to the necessity for operations, treatments and so on, it is impossible to allow more than a certain number of men to take advantage of this training. In individual cases we are able to keep the men busy in different ways. For instance one of our men who was almost totally paralyzed complained to me one day that he was very bored by reading novels and magazines, his only form of amusement for many months past. On questioning him then I found that he had graduated from a high school before the war and that he was interested in civil engineering. He was delighted when we got him an instructor from Columbia University, who kindly tutors him in the evenings, and he is definitely pursuing the freshman studies in civil engineering. His improvement in every way has been remarkable since he took up this work.

We have a division of placement. Needless to say we do not attempt to place men directly, but we consult with the men and try to find out if they have any leaning toward or talent for any special occupation. We are greatly helped in this work by an Advisory Board made up of prominent and successful men in various industries and professions who will talk with the men we send to them and explain the opportunities and the requirements of special lines of work. Having gained as much information as we can, we present the case to the Federal Board who are kind enough to accept our suggestions. We feel that this is a most important part of our work, though one that requires the utmost patience. So many of these boys have not the slightest ideas as to what work they would like to go into, and often when they have desire for some occupation that occupation will be so totally beyond their abilities and educational endowment as to be well nigh hopeless. We also suffer from the tendency in the men to change their ideas as to occupation. One week they want to be one thing, the next week another. We feel that this problem can be handled only by getting to know the men very intimately, by adopting a sympathetic and helpful tone, no matter how big the discrepancy may be between what the boy desires to do and what he is fitted to do. We have endeavored to have supplied to the men the psychological tests which have been so successful in the army, but as yet have failed to get an expert to do this work. We feel strongly that if in the very beginning, the man's training for a definite pursuit could start in the hospital, much time and energy could be saved, but as yet there seems to be no practical method by which this can be achieved, except in rare instances. We hold before the man the necessity of taking advantage of the generous offers which our Government is making and try to get the men to take advantage of them. In the case of our civilian patients we cooperate with various occupational employment agencies and organizations that are equipped to handle this subject.

We have a primitive division given over to education. Our object here is to encourage men to attend lectures on various educational subjects, laying special stress on those dealing with citizenship and matters of public welfare. We have classes in English and try in every way to get the foreigners to learn to read and write and speak English. We have classes in French which have, however, a small attendance. Our classes in Spanish are the most popular, and it is interesting to note that a large number of men feel that South America will eventually provide them with the most prominent field for thier energies. They are also appreciative of the demand for interpreters in Spanish, and we feel that this offers a broad field of usefulness to a handicapped man, for the supply of interpreters in Spanish is so short that even those who have little education can earn $80 to $100 a month. If our relations, commercial and otherwise, with South and Central America continue to enlarge, there will be an increasingly large field for interpreters. Apart from the classes, men are encouraged to go to the various museums in the city, and a guide is provided if they wish. We have been very much im-

pressed with the number of men who take advantage of this.

We have a division of sport and physical exercise. Each morning every men capable of doing so, even though he cannot go through all the movements, is obliged to take a general setting-up drill. This has been one of the most important things we have inaugurated, as aside from his physical effect, the moral effect has been most excellent. Men who for months have been sitting around smoking find once more they are capable of actually exercising various parts of the body. Men are encouraged to play hand tennis, punch a bag, etc. By far the most popular game we have provided, however, has been pool. The pool table is in constant use from early morning until lights out, and it is quite interesting to observe how men who are very seriously handicapped become able through persistence to play this game. It affords a most wholesome form of recreation.

Probably one of the most important services the Social Service Department is able to render to the men is a consideration of their personal problems. Sometimes through neglect or lack of understanding on the part of the individual he may not have received back pay for a number of months. We find it a matter of comparative ease to communicate with the proper authorities and see that he receives his pay. A most extraordinary number of difficulties too diserve to mention can often be straightened out for him. This work, because of its detail, occupies the services of one person most of the day.

A weekly meeting is held which is attended by the chief workers in the different divisions and the members of the Advisory Committee. At these meetings the cases of individual men are brought up for discussion and the work in general gone into, so that workers are in touch with all that is going on in the Clinic.

In conclusion I should like to be put on record as emphasizing the importance of such social service in the rehabilitation of the handicapped. I do not see how the innumerable problems in the handling the individual men can be solved by any other branch of the hospital organization.

5 Livingston Place.

FURUNCULOSIS OF THE EXTERNAL AUDITORY CANAL.

By HUGH B. BLACKWELL, M.D.

NEW YORK.

SENIOR ASSISTANT AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY.

Boils of the auditory canal occur most often during the spring and summer months, and at times in such numbers as to appear almost epidemic in character. The pain attending this condition may be such a marked and early symptom and the demands of the patient for relief so urgent that the general practitioner ofttimes finds himself confronted with the necessity of diagnosing and treating the complaint.

Symptoms.—Each furuncle is divided into an early exudative and a later or suppurative stage. The pain varies according to the depth of the inflammation. Should the infection start in the region of the perichondrium, it is initiated by an ever increasing, throbbing, tearing pain, most severe in character, radiating from the ear and extending over the side of the head or face. It may be accompanied by a loss of sleep and some rise of temperature. When only the superficial layers of the skin are involved there is usually little or no pain. The exudative stage may terminate in resolution, or after a variable time, usually four or five days, depending on the thickness of the overlying structures, the tissues soften, break down with pus formation, and more or less pointing of the abscess takes place on the surface of the canal epithelium. The pain is greatly increased either by pressure over the tragus, traction of the auricle, or upon mastication; this is a valuable point in diagnosis between furunculosis and middle-ear abscess.

Aural Examination.—By the careful use of a small speculum the drum head may frequently be observed. Other than the presence of sympathetic congestion, it should be quite normal in appearance. There is a sensitive swelling on one of the canal walls, which may be indurated or soft, with evidences of pointing, depending on the stage of inflammation at the time of observation. The swelling is sometimes so slight as to be altogether out of proportion to the severity of the pain. At the height of the inflammation there is usually some sensitive enlargement of the lymphatic glands in the region of the auricle.

Course and Duration.—Furuncles of the canal are sometimes multiple and apt to recur in crops. After the evacuation of its contents each boil as a rule undergoes rapid healing, the duration of the entire cycle of development and cure of a furuncle of the canal being about a week.

Treatment.—Ordinarily during the exudative stage the canal should not be incised, save in instances of great pain caused by marked swelling and undue tension. For the relief of pain in furuncles of the canal, the external application of heat is one of the most grateful and soothing remedies we can employ, *e.g.* hot water bottle, salt bag, or electric pad. Sometimes a small conical piece of ice covered with a layer of gauze held in the canal for a few moments acts in much the same favorable manner.

Packing the canal lightly with a strip of plain gauze, impregnated with one of the essential oils, camphor or menthol, frequently affords relief in the early stages of a boil. During the exudative stage the daily use of wet boric-acid dressings either hastens resolution or tends to encourage an early localization of the abscess with pointing. They are applied by packing the canal with a small strip of plain gauze wet with this solution; external to this packing there is placed in the concha a piece of cotton moistened in the same way and changed as often as it becomes dry. Should there be much swelling about the external ear the entire auricle is best covered with wet boric-acid gauze kept moist by using rubber tissue, the entire dressing being held in place by means of a bandage about the head.

When signs of pus or pointing appear, the abscess should be incised and its contents evacuated; this is usually succeeded by a rapid amelioration of all of the acute inflammatory phenomena.

Medical and Surgical Lessons of the War.

NATIONAL ORGANIZATION OF REHABILITATION OF THE DISABLED IN ITALY.*

BY PROFESSOR VITTORIO PUTTI,

BOLOGNA, ITALY.

PROFESSOR OF ORTHOPEDIC SURGERY IN THE UNIVERSITY OF BOLOGNA; DIRECTOR OF THE RIZZOLI INSTITUTE.

THE work done by Italy for soldiers crippled in battle is so vast and complex that it will be a difficult task to give briefly an exact idea of it. Now that the war is over, it may seem superfluous to refer to what was accomplished during a period which we hope may never again be repeated; but we think the work achieved should be divulged because it can serve as a basis and outline for that more extensive and lasting work which is expected now for the betterment of industrial cripples.

We have, therefore, enthusiastically accepted the honorable invitation of the American Red Cross because we realize that in no other country as much as in this one, where the enormous industrial development brings the number of accidents during work to a formidable sum, can the knowledge of our experience be more useful and beneficial. The United States, which is a leader of civilized nations in the matter of social welfare, taking advantage of the example of European countries, will soon discover new ways and methods to succor those who are crippled in the various branches of industry.

From the beginning of the year 1915, when Italy had not yet declared war, throughout the entire country the grave question of the assistance of the disabled was discussed. By means of publications, lectures, meetings, the public was kept in touch with the very important problem and convinced of the necessity for a thorough collaboration toward the performance of the high duty. The country responded with unanimity of opinion and before the end of the year committees were formed, sufficient funds had been collected for the establishment of the first societies for the moral and material relief of the war's disabled. In Italy, as in many other countries, the development of these organizations for the social welfare of these handicapped men is all due to the initiative of private individuals.

Before the war, Italy had no institution whatsoever which could serve as an example for future work. In Milan, alone, there existed a school for the vocational education of disabled civilians, which, however, could aid only a very limited number of patients; there were not lacking, though, men experienced in this regard, to whom we owe the rational and practical methods adopted from the beginning by Italian organizations. In order that the committees in the various regions of Italy might work with uniformity of standards, in 1915, at Rome, there was founded the Federation of Committees for the Relief of the Disabled, and to this organization goes the credit of intense propaganda and the collection of huge funds.

The larger cities of Italy were immediately provided with institutions especially suited to the cure and training, both functional and vocational, of the handicapped men. Among these the principal ones are Milan, Palermo, Bologna, Turin, Florence, and Rome. Soon this example was followed by other centers, and there sprung up schools in Genoa, Pescia, Naples, Pisa, Leghorn, and Venice. But in the place of private initiative came the Government's action.

The task was undertaken on the one hand by the War Department, and on the other by the National Commission for the Relief and Protection of the Disabled, provided for by the law of March, 1917. This law not only provides for the technical reeducation, but also for the important and complex problem of the aftercare and social assistance of the individual, whether he be incapacitated by injuries or disease.

I do not think it necessary to dwell at length upon the description of the work during the first periods of medical care.

From the field hospital the disabled soldier is sent to the base hospital, especially built for this purpose. The selection of the hospital is made according to the custom of sending the injured man nearest his native town or his family.

There are exceptions made to this mode of selection in the case of the so-called *ultra disabled*. These are the men who, on account of the seriousness and quantity of injuries, are not only unable to readapt themselves to any kind of profitable labor, but cannot even provide for themselves the necessities of life.

Sent on to Florence, these ultra disabled find refuge in a rich and sumptuous villa, in the thick of the woods, and there enjoy all the advantages of a moderate climate.

In the base hospitals for the disabled, the cure is completed by the psychotherapic and orthopedic treatment, with a view to reducing to a minimum the effect of the injury, and to preparing the stump for the application of the artificial limb. From this moment the work of encouragement of the disabled begins, with the object of convincing him that he is still capable of profitable labor, of inducing him to retrain, of entertaining him, and diverting his thoughts from his injury. A few of the halls in the base hospitals are set apart for this purpose and turned into laboratories and classes; these are maintained by civilian committees which take an active interest in the work of technical training and after-care. When the patient is pronounced physically cured, he is given one month's leave before commencing his reeducation. This period of leave has been found advisable not only to give the patient the liberty to return to his family and friends, if he so desires, but especially to give the temporary artificial limb enough time to produce on the stump the transformations which are necessary for the fitting of the final appliance.

As to this method which has been followed in Italy, with regard to the construction of artificial limbs, I will not now go into details, because this subject will be more fully treated by me in another report. The production of artificial limbs, which was at first insufficient as to quantity and poor as to quality, is now completely satisfactory. The really remarkable progress made by Italy in this

*A paper presented at the International Conference on Rehabilitation of the Disabled, under the auspices of the Red Cross Institute for Crippled and Disabled Men, Section XVI, New York, March 18 to March 21, 1919.

field was universally recognized at the London exposition, May, 1918, on the occasion of the Interallied Conference.

Both the War Department and the National Commission appointed committees composed of persons competent in orthopedics, and of representatives of the Association of the Disabled, who were to control the work of each factory for the construction of artificial limbs. Recently the War Department has adopted a standard type of appliance for use in the case of amputated lower limbs, which has not yet been tested. Two central commissions residing in Rome are entrusted with the problem of encouraging new developments in the construction of artificial limbs, by examining models submitted, by organizing contests, etc.

At the end of the physical and orthopedic treatment the disabled man remains in the school for vocational training. This reeducation is not compulsory in Italy, but the law commands that each man, after having recuperated physically, pass at least fifteen days in the training school. This provision of the law, which has been made by the government upon the example of the Bologna School for Vocational Training, allows the invalid, perhaps ill-disposed toward this reeducation, to witness its good effects, and results in the vocational training of a far greater number of men. To give an idea of the tendency of the disabled to undertake vocational education, I will say that in the Bologna School sixty per cent. of the handicapped have accepted to be trained.

These schools, although founded by private initiative and local committees, are under the control of the War Department and the National Commission. The War Department since 1914 has appointed a special inspector in the person of Professor E. Burci, president of the Italian Section of the Interallied Committee, whose aim it is to combine the work of the military authorities with that of the local committees and distribute equally the material and spiritual assistance to the handicapped. The National Commission has control over the reeducation schools, through local committees, which during the first period of the war spontaneously undertook the establishment of vocational schools. It is a fact worthy of note, that there exists in Italy a flourishing Association of Disabled Soldiers and Sailors, with a membership of about 50,000, which acts in strict unison with the military authorities and with the National Commission in all that regards the social welfare of the disabled.

In view of the enormous expense entailed in the adequate development of the training schools, the government has granted the committees a daily subsidy for each disabled man, amounting to 3.50 Italian lire for the indoor patients, and 2 lire for the outdoor patients for a stated period of not more than six months. In many cases, however, this period of time is much too short for a complete training, and under those circumstances the local committees provide out of their funds the amount required for the maintenance of the injured during his entire stay at the institution.

The committees generally grant a small daily allowance to their pupils, about one lire; part of which is put into savings banks and given to the disabled man when he leaves the institution. Various committees, besides, furnish the handicapped man with the tools of the trade for which he has been trained.

We, in Italy, are convinced that the resident system is greatly superior to the non-resident system, and we have, therefore, put the former into more extensive practice. Experience has also taught us that the larger institutions are more efficient than the small ones, and the National Commission has, therefore, decided to give the maximum support to the more active and best-organized of them.

Our disabled generally find in the schools the training they require. The more common trades taught are: shoemaking, tailoring, saddlery, carpentry, mechanical trades, bookbinding, etc., furthermore, all trades indigenous to agricultural districts as, for instance, basket-making, cartwright, and copper trades, etc. Then there are also the commercial courses: bookkeeping, typewriting, drawing, telegraphy; all the disabled are compelled, besides, to attend elementary courses of study for a few hours each day.

In dealing with the disabled man in the choice of his occupation, I will quote the conclusions to which Mr. Chevelley has arrived in an important study of the question of which he has acquired a vast experience:

1. Whenever it is possible, the disabled men ought to be retained in the trade followed by them in the pre-war days, or in one similar to it.

2. The above rule ought to be applied especially to agricultural laborers, who constitute in Italy about eighty-five per cent. of the total number of disabled men.

Through the efforts that have lately been made by the League of Assistance committees, and by the individual committees as well, laborers have been induced to return to the land, disabled men having become convinced of the advantages accruing to them and their families by so doing. This is a step, however, to be taken only after the disabled men have learned the use of labor appliances suitable to each particular case, and on their completing a course wherein they have been taught the rudiments of modern agriculture; in this way, and in spite of their physical disability, they may obtain from the land a much better yield than they would have done had they persisted in following the ancient methods.

3. In view of the very large number of disabled men who aim at obtaining small government appointments, the necessity has been recognized of discountenancing their applications, and, by so doing, sparing them many future disappointments; it has been also recognized that it is infinitely preferable to give the disabled men a thorough training in appropriate trades and callings which, besides being of a more profitable and independent nature, are also not quite so much sought after.

4. The authorities have also come to realize the necessity of discouraging the tendency which has increased to big proportions, of crowding into the cities. This has been obtained by persuading the disabled men to return to their native towns or villages as much as possible.

As far as regards the agricultural training, which, naturally, is of so great importance in Italy, in spite of the good attempts made here and there,

it is still very far from being considered with that broad-mindedness and seriousness which it deserves. Many reeducational schools are provided with specially organized departments for agricultural training; as, for example, Florence, Genoa, Leghorn, Modena, Pisa, Rome; then there are the agricultural branches in the professional colleges, which as a consequence of their development have assumed an almost autonomous management, as, for instance, the schools of Milan, Palermo, Pescia. And finally, we have the schools exclusively dedicated to agricultural training of handicapped men, as in the case of Ancona, Lecce, Perugia, Voghera, and Turin. However great this number of schools, their efficiency is very poor and we are still very far from obtaining those good results which we were somewhat entitled to expect.

The problem of placing the reeducated man has been carefully studied in Italy. To take the place of the local committee's action soon came the National Federation of Committees, through whose influence was formed the central employment office, which quickly gave truly remarkable results.

To these various relief organizations later came the aid of the National Association of the War's Disabled, whose constitution had not overlooked the great essential item, *i.e.* the employment of its members.

The action of the government for the solution of this grave question came later and took the form of the law of March 25, 1917, of which I have made mention, and which indicates to the National Commission the plan to be followed in placing the remade man.

According to the new law, soldiers who, in accordance with the existing regulations have been declared disabled may, when their disability allows, remain in the army with the military authorities' consent.

With regard to the readmission and admission into public offices and works, the facilities which the law grants may be divided into three categories: the right to readmission to the offices, the bestowal of posts without competition, and the preference in competition where talent or attainments are equal.

Another opportunity granted by the law is that on the basis of which the condition of being a disabled man constitutes a right to precedence in the case of equality of talent and qualifications in the graduation of competitors for admission to public employment. Facilities of a general character have also been granted both by law and regulations which are intended to give aid to the disabled in obtaining employment by private concerns or individuals.

In the concessions of posts or scholarships not destined to benefit any designated families, preference is given to the disabled, and, on the same terms as the other competitors, to their children. As far as is applicable, the legal privileges obtained for war orphans are extended to the children of the disabled.

It is finally stated that all accident insurance, taken out in connection with the work of disabled, reemployed in any kind of factory, is compulsorily assumed by the insurance institutions, and that in the employment of the disabled, as element for the valuation of the risk, this would become necessary only if their number exceeds a certain limit.

As regards the pensions, I can only give you here a very short account of what Italy has done. This matter was adequately treated, from all points of view, by Major Giuriati, at the Interallied Conference, at London, in May of last year.

The problem of the distribution of pensions is now entirely in the hands of a department especially created in November, 1917.

According to the regulations that formerly existed, the different degrees of disablement were classified in three separate categories only; such an arrangement was far from being in accord with the variety and extension of the subject. For each one of these categories, as was prescribed in the past, a stated amount used to be contributed as indemnity; such an amount was by no means a just or proportionate value, and as a result either the soldier or the government has to sustain serious financial loss.

According to the former regulations, it was understood that the title to pensions was limited to the men's unfitness for military service. This has been substituted for the larger conception of the men's greater or lesser fitness for the undertaking of lucrative labor.

The government's intention is to compensate the individual for the diminishing of his powers for lucrative work, and proportionately to his physical disablement.

Consequently the different degrees of disablement for which pensions are now given have been subdivided into ten categories instead of only three as heretofore; this is proving a much easier arrangement, and infinitely more in proportion to the exigencies of the different cases.

According to the first eight categories, the subject is entitled to a pension, while for the last two he receives a temporary allowance. The former refer to permanent disablement of a greater degree, which minimizes the working power of the individual. The allowances are given to men suffering from lesser degrees of disablement, which cause a much smaller reduction, if any, of the individual's earning capacity.

In cases referring to a presumable modification or aggravation of the degree of disablement in so far as they may affect the men's working capacity, the decision stating the amount of pension to be paid can be twice revised within the period of five years.

The current regulations tend to facilitate in every way possible all the proceedings, which have been greatly simplified. The facts are submitted to only one medical board, and the interested party has seven days allowed him to consider their decision, either favorably or the reverse. Should he refuse to accept it, the matter is referred to a Commission of Appeal, which consists of one of the directors of the Military Board of Health, of two army and two civilian doctors, one of the latter being appointed by the National Association among the disabled men, the other by the local committee dependent on the Ministry of Pensions and of Military Assistance. In this manner both the interests of the soldier and of the government are safeguarded.

A further modification has been brought with regard to ascertaining whether or not the injury is

due to service reasons. This has been greatly facilitated by the acceptance, as evidence, of the declaration of one of the hospital directors or of one of the commandants of the regimental depots.

So liberal an interpretation has now been given to the conception of service reasons that the very fact of the man having been on duty is considered sufficient, and this has been of enormous importance with respect to disablement caused by illness (tuberculosis).

The maximum rate of pensions is allowed for disablements included in the first category (100 x 100). As for the disablements included in the other categories—from the second to the eighth inclusive—they are calculated proportionately at 80, 75, 70, 60, 50, 40, and 30 per cent. of the pensions allowed for the first category.

Whenever the degree and nature of his disablement cause the soldier to require the assistance of another person, he is entitled to a supplementary allowance over and above his pension.

The disablements belonging to the ninth and tenth categories call for a temporary allowance, instead of the pension for life. This allowance is equal to the amount of the pensions belonging to the eighth category, payable in one lump sum, and calculated for a period that varies from a minimum of six months to a maximum of six years.

I must say a few words before terminating, on the assistance given the blind, the mutilated in the face, and the tuberculous.

The Blind.—At Milan, Florence, and Rome, concentration hospitals for the blind have been erected. From these hospitals the soldiers pronounced completely and irreparably blind are transferred to the special hospitals or schools in Florence, Rome, Naples, Milan, Padua, Catania, according to the locality of their birth, for their reeducation or aftercare.

The work of the reeducational school is greatly simplified by a disposition of law which provides that the blind soldier, when still in the concentration hospitals, be given a practical view on his new life and a methodical sensorial education.

In the vocational schools the trades most frequently taken up are: Cane chairmaking, brushmaking, shoemaking, bookbinding, wood carving, etc.

The choice of the trade, though often made by the Council of Directors of the schools, after an adequate test period, is left free to the injured. The work of the blind is generally simplified by the use of special apparatus.

In the Vocational School at Florence much experimenting has been done, and successfully, with training the blind for agricultural occupations. At Rome the wood and leather trades have succeeded best. The more cultured blind are encouraged to become masseurs, linguists, musicians, or office employees, as typists, etc.

From the employment point of view, Signora Mondolfo, who has shown an intense interest in this end of the work, maintains that the blind man should be induced to take up individual autonomous work, whether at home, in the factory, in the office, and among persons who have their sight.

Assistance to the Tuberculous Soldiers.—According to the law dealing with the assistance to the disabled, the patients suffering from tuberculosis are considered as belonging to the disabled class, from both a physical and practical point of view. The question of tuberculosis has been sadly aggravated in Italy since the return of our prisoners of war, who left behind them in the cruel Austrian concentration camps their health and youth, coming back to us only too often inexorably tainted with this terrible malady.

The antituberculous fight was begun by Circular No. 801, of December 20, 1916. In obedience to this document, in every territorial army corps, and at the base of every army in the war zone, special sections for the diagnostic study of incipient or latent symptoms of this malady were created.

The first symptoms having been discovered in time, at these diagnostic sections that are under the management of specialists, the patients are promptly sent away from the ranks of the army and benefit by a whole series of dispositions and provisions especially drawn up with a view to receiving them, treating them, and giving antitubercular instruction.

A medical center for the selection of tuberculous soldiers was at first established at Nervi. This is a big first-grade institution for the gathering together of the numerous tuberculous patients that have been returned to us by the enemy, where the diagnosis is made and the degree of specific lesion ascertained before transferring the patients to other hospitals adapted to their case.

Contemporaneously with the institution of the health center at Nervi, which can accommodate 1200 patients, another center for selection of more than 600 beds was set up in the rear of the war zone, to gather together and select the patients coming from the ranks of the army.

The second sanitary center for selection, organized on the same lines as the one at Nervi, was opened at Careggi, a locality not very far from Florence.

By both these said centers, as in all the other diagnostic sections belonging to the various army corps, the patients are divided into three categories, according to the gravity of the sickness.

As soon as the condition of the men is ascertained, they are received in special tuberculous wards at the different hospitals where these same wards have been instituted in the territories belonging to the different army corps.

The patients who are not so seriously ill are sent to appropriate sanatoria that have been instituted in each territorial army corps, where they are kept for about three months, and where, once this period passed, they are given their discharge. With their discharge, however, the assistance given to this class of disabled men does not cease. As a result of an agreement between the Ministers of War and of the Interior, all these patients are entitled to continue to receive all possible assistance, both medical and practical, unless they end by being recognized as disabled as a result of war service and, as such, entitled to all their pension rights.

The military administration has decided to grant, instead of the bonus, equal to a year's pension, that they used to pay now and again to these sick men, an allowance of so much toward their treatment (assistance allowance) every time that the ex-

soldier has to return to the hospital during the three succeeding years after his discharge.

An equal sum is to be paid to each patient by the Ministry of the Interior, so as to total a daily sum equal to 5 lire.

During the detention of the discharged soldier in the sanatorium, the respective families will receive a daily allowance equal to the separation allowance given to the families of the soldiers called up for military service.

With regard to the men who have a latent form of tuberculosis, they are sent to special sanatoria for treatment of initial tuberculosis (climatic institutes) generally under the direction of the Red Cross; of these, there are already three of some importance: Bergeggi near Genoa, Fara Sabina near Rome, and Milanino near Massa Marittima; the patients can remain in these institutions up to six months entirely at the expense of the military administration. Once this period of treatment is over, this same administration reserves the right to have the patients reexamined at the diagnostic sections, where it had been decided to have them sent to these sanatoria, and where further decisions as to the care of the men are taken.

In the help of the tuberculous the government and Italian Red Cross have been materially assisted by the aid of the American Red Cross.

From the very first months of the war, much has been done for the aid of those facially mutilated and those whose nervous systems have been seriously impaired.

For the assistance of the former concentration hospitals conducted by specialists were erected in the war zone. From these the injured are sent to the base hospitals where all the possible aid is given them, not excluding prosthetic appliances. The prosthetic appliances are furnished by the government with the same criteria as that used in the distribution of artificial limbs.

Similar organizations have been instituted for those suffering from impairment of the nervous system.

From the concentration hospitals they are sent to the so called *neurological centers* in the principal cities. Each of the centers is divided into two sections: One for the patients suffering from organic injuries, the other for those displaying neuropsychic phenomena.

These centers are under the supervision of the local committees for moral assistance, technical training, and reemployment; the same routine is followed here as in the case of other disabled men.

During the last months there have been instituted at Milan, with funds collected from public charity, two hospitals exclusively for the moral aid and reeducation of the severely injured in the spinal cord and the brain.

I have given but a pallid idea of what Italy has accomplished and is accomplishing in behalf of her war cripples. Now that the war is over, many of the provisions to which I have alluded have been somewhat modified and must naturally, in time, undergo further changes in accordance with the new requirements.

But the foundation which the nation has built so fervently, enthusiastically, and wisely, will remain to testify, before all the ages, to the magnificent performance of this high duty, and serve as a basis for the future development of the great work in the interest of industrial cripples.

Medicolegal Notes.

Result of Original Injury.—The Michigan Supreme Court holds that where an injured servant's condition of total disability was entirely due to his original injury, the State Accident Fund was not entitled to be relieved from the weekly payment it had agreed to make during disability on the ground that the present disability was caused by unskilful treatment or refusal to submit to an operation. One physician testified that he would consider the applicant totally disabled, and that this condition of total disability was due in large part to the original injury. Approximately the original injury was the cause of his resulting physical condition. He testified that he would state that even if the doctor, who treated this arm some months after the accident, had done the best that could ordinarily be done by a careful, skilled, prudent physician, this arm might still be in a condition resulting in total disability.

There was other medical testimony before the board from which, if believed by the board, it would appear that by submitting to an operation the condition of the arm would be greatly improved, and that thereby he might regain from 25 to 50 per cent. of its normal use. The court, however, said that it did not concern itself with the determination of questions of fact, where there is any competent testimony supporting the conclusions reached by the Industrial Accident Board. It therefore affirmed the order of the board.

Relative Value of Medical Expert Testimony.—On appeal from a conviction of manslaughter by assault, where the principal controversy was whether the death was caused by the assault or by disease, counsel for the accused contended that the trial court erred in refusing to give the following instruction: "The court has allowed in this case the introduction of expert testimony as to the cause of the death of Ida Murray. The court instructs you that the opinions expressed by such witnesses are not binding or conclusive upon you. It is for you to determine from all the facts and circumstances in the case what, in fact, was the cause of the death of Ida Murray, and you are not to act upon expert opinions to the entire exclusion of other testimony." The Illinois Supreme Court holds this instruction was properly refused because it tended to cast discredit upon expert testimony. The court said that there can be no question, of course, that the weight to be given the testimony of experts is to be determined by the jury. There is no rule of law which requires them to surrender their judgment or to give a controlling influence to the opinions of scientific witnesses. Even if several competent experts concur in their opinion and no opposing expert evidence is offered, the jury are still bound to decide the issue upon their own fair judgment, assisted by the statements of the experts. Nevertheless, the testimony of an expert may not be arbitrarily rejected, but, like the evidence of every other witness, it is to be considered by the jurors, who are to accord to it influence, much or little, according as it appeals to their intelligent and impartial minds in view of all the facts and circumstances developed upon the trial and the common knowledge and experience of mankind, and, when such common knowledge utterly fails, the expert opinion may, of course, become controlling. Of course, these declarations are affected greatly by the nature of the particular case under discussion, since expert evidence is far more clearly essential and trustworthy on some topics than on others, in which it may yet be held admissible, and also by the merits of the evidence in the particular case. The court holds that the relative weight to be given to the opinions of medical and non-medical experts cannot be determined by any rule of law, although the strong presumption would be that, where both classes of experts are given the same opportunities for observation, the opinions of medical experts would be entitled to the greater weight.—People v. Harvey (Ill.), 122 N. E. 138.

EXPOSURE AND "COLDS."

THE association between chilling of the body surface and the development of acute pharyngitis, rhinitis, and tonsillitis is one that is so familiar as scarcely to excite comment. The mechanism of the infection is not wholly clear. It has been generally stated that following chilling of the skin surface there occurs a constriction of the superficial vessels and, as a result, congestion of the vessels in the mucous membrane. This is supposed to bring about an alteration in the resistance of the mucous membrane so that the bacteria normally present on its surface are enabled to grow and produce an infection. But careful investigation of the subject has been lacking.

Mudd and Grant have, however, carried on a series of experimental investigations into this subject which seem to show that, in reality, what does occur is the exact opposite; that is, chilling of the body surface is followed by a reflex vasoconstriction and ischemia of the mucous membranes of the tonsils, oropharynx, and nasopharynx (*Jour. Med. Research*, 1919, xl, 53). Their investigations were carried out on human subjects. They adopted the temperature as the criterion of the condition of the vessels and devised a three-element thermophile of copper and German silver wire which could be applied closely but gently to the surface of the skin or mucous membrane. Chilling was accomplished by exposing areas of the body surface to the air, breeze from an electric fan, or cloths wet in cold water. Since this exposure results also in a deepening of the respiration and this in itself has a tendency to lower the temperature of the mucous membranes, it was necessary to control carefully the respirations of the subjects. This was accomplished by the use of a metronome and a pneumograph so arranged that the subject could see the record of the chest and abdominal movements and could voluntarily regulate them, so as to be of constant excursion.

It was found that chilling of the body surface causes reflex vasoconstriction in the skin of the head and neck, but that these vessels "react" promptly and completely after the cessation of the chilling. It also causes reflex vasoconstriction and ischemia in the mucous membranes of the palate, faucial tonsils, oropharynx, and nasopharynx, but here the "reaction" is incomplete and the recovery is very slow. The authors propose the theory that the ischemia incident on cutaneous chilling, "by decreasing cell respiration, or by retarding removal of the products of cell metabolism, or by increasing the permeability of the epithelial cell surfaces to the bacterial products, or by decreasing the local supply of specific antibodies, or by altering the media in the tonsillar crypts and folds of the pharyngeal mucosa, or by a combination of these factors," might so disturb the equilibrium between host and parasite as to excite infection. They also suggest that the surface tension relations of bacteria and mucosa cell surfaces is a subject worthy of experimental investigation in this connection. There is no explanation suggested concerning the failure of the mucous membranes to "react" as the skin does, an ability which would seem to have some protective value. The experiments are all carefully controlled and the results are clear cut. There seems no doubt that the reflex occurs as described.

THE ASSOCIATION OF GRAVES' DISEASE AND DIABETES.

THE association of Graves' disease and diabetes is chronologically rather variable. Nevertheless, in the majority of cases the former syndrome is the first upon the scene. In very few instances has diabetes been followed by the development of exophthalmic goiter, while in eight cases of which we have records, both processes seem to have developed simultaneously and usually a violent emotion had preceded the morbid phenomena. It would appear, from the present state of our knowledge that the association of Graves' disease and diabetes is rather uncommon, although some writers, Apert among others, maintain the contrary opinion. Out of a total of thirty-two cases of exophthalmic goiter, Griffith found glycosuria in only two and Naunyn states that he never discovered it in the many cases of Graves' disease treated at the medical clinic of Strasbourg. Out of a total of ninety patients with exophthalmic goiter, Sainton found only three who had a manifest glycosuria and these cases were complicated by hypophyseal and suprarenal disturbances. Thompson found sugar in three cases out of eighty and Billings in one out of sixty-one cases. Kocher declared that he had never met with a case of diabetes in the numerous cases of exophthalmic goiter operated on by him. Gastand estimates that 3 per cent. of cases of exophthalmic goiter are associated with diabetes.

It would be of great interest to know what becomes of these patients, but unfortunately most of the case reports published so far are incomplete and give no details in this respect. According to Sattler, twenty-five of these cases resulted quite speedily in death, seven occurring in diabetic coma, while six others died of tuberculosis and one from pneumonia. In quite a few instances, the diabetes arose in long-standing cases of Graves' disease, and it

can be said that diabetes develops in general a long time after the onset of the first symptoms of exophthalmic goiter and in some instances the glycosuria appeared when the other syndrome was on the wane. On the other hand, it has been noted that when the two processes evolute together during a certain lapse of time, the sugar decreases if the symptoms of exophthalmic goiter suddenly increase.

The symptoms of diabetes usually encountered, when in association with Graves' disease, are polyuria, polyphagia, polydipsia, and glycosuria. The polyuria is very considerable and may attain fourteen liters in twenty-four hours.

In the serious forms the amount of sugar will be more than 6 per cent., but more often the glycosuria will be moderate. An interesting fact is the rapid reaction on the patient's physical condition when the diabetes appears. Rapid emaciation is frequent and from the onset of the glycosuric symptoms the patients complain of extreme fatigue and profuse sweating upon the slightest exertion. As less frequent complications, acetonuria and diabetic coma are to be noted. The latter appears to be the final outcome of the more serious forms, which may also terminate in marasmus with extreme cachexia. Therefore the appearance of the symptoms of diabetes must be regarded as a complication which singularly aggravates the prognosis of exophthalmic goiter.

As to the sex and age, it is well known that Graves' disease is more common in the female and that, on the contrary, diabetes has a marked predilection for the male sex, usually appearing at a rather advanced age, between forty and sixty years. Now the association of the two morbid processes is met with more frequently in the female, and if the age is taken into consideration, the figures come near to those we have of diabetes, while from twenty to forty years of age generally represents the maximum of morbidity in Graves' disease, particularly in women. The mortality in cases of exophthalmic goiter associated with diabetes is far higher than in simple Graves' disease and this is only what might be expected.

ALKAPTONURIA.

ORDINARILY, alkaptonuria does not react upon the general health and is not accompanied by any functional disturbance. At the most we may find some disturbances of micturition observed by Stange, such as vesical pain, tenesmus, painful micturition, and sensibility of the perivesical area, which appear to result from the action of the homogentisic acid on the vesical mucosa, but in Stange's cases the alkaptonuria was very pronounced. Embden took eight grams of homogentisic acid and suffered from atrocious tenesmus; Stier took six grams in the morning and the above symptoms appeared at two o'clock in the afternoon. Others have experimentally experienced the same train of symptoms. Usually it is only by chance that attention is drawn to the dark tint of the urine or it declares itself by the dark spots caused by it on the patient's linen. Alkaptonuria is met with quite as frequently in children as in adults, and is apt to last during the lifetime of the subject without giving rise to untoward symptoms or complications. Very often it is intermittent. Geyger found it in a diabetic during one day only, Moraczewski for a few days before death in a tuberculous subject, and Hirsch during three days in a woman with an acute gastroenteritis.

The process must be regarded as due to a defective metabolism resulting from an insufficient secretion of the hepatic autolytic ferment, which is necessary for the complete combustion of albuminoid matter. In reality, this is merely an hypothesis, but it seems to contain at least a part of the truth. The characters of alkaptonuric urine are clearly sufficient for making a diagnosis. It is, in reality, of little import because, as has been said, the condition may coexist with an apparently perfect state of health. The only interest of this urinary change is that it may cause a possible confusion with diabetes and its relationship to ochronosis. A typical example of this mistake was published by Osler in a family of which one of the brothers was the first alkaptonuric observed in the United States. Wishing to take out a life insurance policy, he was examined and it was found that his urine reduced Fehling's solution. A diagnosis of diabetes was consequently made, but a further examination of the properties of the substance in the urine, which caused the reduction, led to a rejection of this diagnosis. A brother of this man—an active business man—who was supposed to be diabetic, went to Europe in 1894. There he had an attack of cardiac arrhythmia, which was declared to be diabetic, but after a season at Carlsbad he went to England, where a diagnosis of alkaptonuria was made.

Such errors are possible, but a careful analysis of the urine should be enough for avoiding them. The characters of diabetic urine are too well known and those of alkaptonuria differ in many respects. The specific gravity is never as high as in diabetes and the polarization plane is not deviated. Both alkaptonuric and diabetic urines reduce Fehling's and Trommer's solutions, but the indifference of the urine to polarize light, its normal or slightly high specific gravity, and its resistance to fermentation in presence of beer yeast, are enough to eliminate the question of diabetes.

THE EVOLUTION OF GONORRHEAL KERATOSES.

THE characteristic features of this complication of gonorrhea are not merely the very special type of the eruption, but also the nature of the soil upon which the cutaneous manifestations develop. The gonorrhea is not a normal one but of the very infecting type, the joint manifestations of which affect a characteristic evolution. Subjects presenting a gonorrheal keratosis always offer serious multiple joint complications, such as seropurulent arthritis or arthritis with marked amyotrophia. But al-

though serious and stubborn to treatment, these arthritides never end in ankylosis as is very generally the case in gonorrheal types of joint infection. It may well be possible that the production of keratosis is a process similar to that arising in the joints and ending in ankylosis and that the cutaneous lesions act as a kind of derivation of the morbid process in the joints. However this may be, the papulæ of keratosis occur in attacks. In the midst of large adult elements very minute ones are seen to appear and as the joint phenomena subside, so do the cutaneous lesions. These particular gonorrheal subjects usually offer a clinical picture rich in complications—conjunctivitis, pericarditis, endocarditis, aortitis, nephritis, purpura, azoturia, and a more or less pronounced state of cachexia. These horny cutaneous lesions may recur with the advent of a new gonorrhea and it is precisely this recurrence that called the attention of the first one to describe the process—namely Vidal—and caused him to consider the gonorrheal origin of this form or keratosis. The diagnosis is usually easy to make and when once this complication has been encountered it is practically impossible to err again. In point of fact, the multiple joint lesions in a cachectic gonorrheal subject, the horny symmetrical cutaneous productions on the plantar aspect of the foot, the yellowish transparent cones with, occasionally, a trifling erythematous border at their base, their relief above the surrounding cutaneous surface and the absence of evidences of syphilis—negative Wassermann and failure of specific treatment—will permit the clinician to make the diagnosis. The lesions of gonorrheal keratosis end by desquamation, and since the joint lesions do not usually result in ankylosis, the prognosis of this cutaneous complication of gonorrhea may be considered good.

Abortive Forms of Recklinghausen's Disease.

An article by Adrian and Hügel on this subject in the *Annales de dermatologie* for May is of incidental interest because it indicates that the French are again in control of the University of Strasbourg. The thesis of the authors is best indicated by an illustrative case. This occurred in a young girl operated upon in 1910, when aged 14, by some German surgeon for ileocecal tuberculosis. When seen later the entire surface was studded with pigmentations which, according to the parents, went back to infancy. The mucosæ were exempt. There was not the slightest trace of a cutaneous tumor nor of any anatomical implication of the nervous system. The girl was normal mentally, but stunted in growth and with a suggestion of rickets. There were evidences of infantilism, the breasts being undeveloped as well as the pilous system. Both parents had been markedly tuberculous and there was a high degree of child mortality in the family. An examination of the mother and surviving children revealed normal intelligence. This case by itself would prove nothing, and it is only by comparison with numerous others that we arrive at the true nature of such phenomena. Congenital pigmented nevi must in certain individuals come to be regarded as abortive Recklinghausen's disease, despite the absence of anything to suggest plexiform neuroma. In this malady there are many phenomena which stop short of these growths and yet suggest strong kinship. The diagnosis in such cases is in fact made by exclusion. It is odd that in the author's two cases there is no history of hereditary transmission. There is, however, a notable history of degeneracy in these cases. While the evidence for the existence of the alleged disease is somewhat weak, it is well to seek for unicism as well as dualism in medicine, for both factors are strongly at work. The new disease of the moment may turn out to be some old affection in a new form.

News of the Week.

The International Conference of Women Physicians.—This conference which is being held at the headquarters of the Young Women's Christian Association, 600 Lexington Avenue, New York, was opened on September 15 by an address by Mrs. Robert E. Speer, president of the National Board of Young Women's Christian Associations and chairman of the Social Morality Committee. The conference was called in response to the situation created by the war, which has changed the public attitude toward health questions. Women doctors have come to recognize the need of establishing the health and strength of women on a higher level and of recognizing that women must have greater physical stamina if they are to make an effective contribution to industry and business without injury to the oncoming generation. The exigencies of the war also brought out the fact that the ignorance of women in matters of sex, and their lack of understanding of their own emotional impulses, were bound up with their physical weakness. Hence the object of this conference is to consider the ways in which the physical condition of women may be improved and their ignorance and immaturity of attitude toward sex and emotional health eliminated. All the subjects brought before the conference are being discussed, not from the research point of view, but from that of their practical bearing on the problem of the development of a more vigorous and responsible type of woman. The conference will be continued with periods of intermission, until October 15. It is then planned to summarize the conclusions of the discussions and to present the results in condensed form to a Convention of Delegates from leading national women's organizations in this country who have shown interest in the problems discussed to the end that there may be cooperation among all women in achieving those changes in the lives of women which determine not only their health but their capacity for a more abundant life. It is planned to continue the convention discussions until October 15. During the intermissions trips are being taken to various hospitals and institutions in and near New York and a four days trip to Boston has been planned for the overseas delegates. During the first week of the conference such subjects were discussed as "Health and Personality," "Physical Examinations as a Means of Health Education," "Exercise—Most Neglected Health Habit," "Dress as an Index of the Position of Women," "National Food

Economics," and "Vitamines." Among the foreign delegates present are the following: Dr. Mary Gordon, England; Dr. Francis Storrs Johnston, Scotland; Dr. Dangy Bang, Norway, Dr. Martha Regina Stang, Norway; Dr. Yvonne Pouzin, France; Dr. Natalie Wintsch-Maleeff, Switzerland; Dr. Ada Potter, Holland; Dr. Alma Sundquist, Sweden; Dr. Clelia Lollini, Italy; Dr. Tomo, Inouye, Japan; Dr. Ida Kahn, Dr. Dau and Dr. Li Bi-Cu, China.

Doctors Asked to Volunteer to Combat Influenza.—The United States Public Health Service, through the various State Health Departments, is calling upon doctors to volunteer their services exclusively to prevent a recurrence of last year's epidemic of influenza. Physicians will be used, as far as possible, in their own States and in their own communities. The doctors who volunteer will be paid $200 a month, in addition to an allowance of $4 a day for expenses. Two hundred and seventy-five cases of influenza were reported to the United States Public Health Service for the week ended Sept. 13. These are the States from which reports have been received: Alabama, 6; Arkansas, 29; California, 32; Connecticut, 2; Florida, 26; Georgia, 34; Kansas, 19; Louisiana, 33; Massachusetts, 46; Montana, 4; New Jersey, 17; New York, 24, and Washington, 3.

Conference on Prevention of Influenza Epidemic.—During the week of September 15 a conference was held in New York City at which a number of bacteriologists agreed to combine their efforts in a study of the causative agent of influenza. This conference marks the beginning of a Federal, State, and municipal effort to prevent the recurrence of an epidemic of influenza. Those at the conference were Dr. William H. Park, Director of the Laboratories of the New York City Department of Health; Dr. George W. McCoy, Director of the Hygienic Laboratories of the United States Public Health Service; Dr. M J. Rosenau, professor of hygiene and preventive medicine in Harvard University, and Dr. E. O. Jordan, professor of bacteriology in the University of Chicago. Following the conference Dr. Copeland announced a circular of instruction will be distributed through the New York schools for the information of parents and guardians as to measures that may be helpful in preventing the spread of influenza. Physicians are urged to report all cases of influenza met with to the Board of Health, and vaccines will be distributed to physicians on request or administered to those who may desire them at the Board of Health clinics.

Former Minister to China Will Fight Opium Traffic.—Dr. Paul S. Reinsch, whose resignation as United States Minister to China was accepted by President Wilson some time ago, has pledged the International Anti-Opium Association that he will endeavor to prevent Americans from sending morphine to China by way of Japan He has expressed his sympathy with the work of association which seeks to free China from the evils of morphine which he states, are greater than those of opium.

Positions for Physicians Under the Interdepartmental Social Hygiene Board.—The United States Civil Service Commission announces that the recently created Interdepartmental Social Hygiene Board of the United States Government is in need of trained men and women to fill the following positions: Chief of division for scientific research, $3,500 to $4,500 a year; chief of division for educational research and development, $3,500 to $4,500 a year; educational assistant, $2,800 to $3,600 a year; chief of division of relations with States, $3,500 to $4,500 a year; chief of division of records, information and planning, $3,500 to $4,500 a year; supervising assistant and inspector, $2.800 to $3,600 a year; field agent, $1,800 to $3,000 a year. All positions are open to both men and women. Applicants for these positions will not be given scholastic tests in an examination room but will be rated upon their education, experience, and writings. Published writings of which the applicant is the author will be submitted with the application. Detailed information and application blanks may be obtained from the United States Civil Service Commission, Washington, D. C., or from the secretary of the United States Civil Service Board at the post office or customhouse in any of 3,000 cities.

Alabama Public Health Bill Meets Opposition.—The Alabama House and Senate committee on Public Health held a hearing on August 20 at which the public health bill which had been introduced into each house was discussed. The bill met with violent opposition because it transfers to the members of the Alabama Medical Association very "strong powers," which the opposition claim should remain with the people. The bill contains a clause which it is held delegates certain powers of boards of revenue and city governing boards to county health boards. A petition was presented asking that the committee take the health department from the control of the State Medical Society. The committee adjourned without taking any action.

Physicians Advance Fees—The physicians of Bangor, Me., have adopted a new schedule of fees which went into effect on September 1. The new fees are: Office consultation, $2; house visits, day, $3; night, after 8 o'clock, $4; consultation, $5. Bangor is said to be one of the last cities in New England to advance fees. Middletown, Conn., physicians have as yet made no advances in their charges for medical attendance. At a recent meeting of the Central Medical Association, a special committee presented a report on fees which was accepted and tabled indefinitely which means that the schedule in that locality is the same as that adopted twelve years ago. From Tennessee comes the report that the physicians of Columbia have entered into an agreement to raise their charges for both day and night calls. The charge for day visits is raised to $3 and for night visits to $4. The charge agreed upon for a normal obstetric case is $25.

Scholarships Open to Negroes.—The General Education Board of the Rockefeller Foundation announces that it has just sent to the deans of all medical schools in the United States where there are negro students the details of an opportunity for especially qualified negro students to benefit by six scholarships to pay their expenses during post-graduate work in advanced study in

such fundamental medical sciences as pathology, bacteriology, physiology, pharmacology, physiological chemistry, etc. These scholarships are offered by Mr. Julius Rosenwald of Chicago, and are each for $1,200 a year. The institution at which the fellowship holder is to study and the line of work he is to pursue are subject to the approval of a committee. Application may be made to Abraham Flexner, Secretary of the General Education Board, and should contain a full account of the education, general and professional, of the applicant, including a transcript of his entire record in the medical school. The appointments will be made in 1920.

Framingham, Mass., Reduces Sickness and Death Rate.—At a recent conference in the offices of the Metropolitan Life Insurance Company in New York, Dr. Donald B. Armstrong reported the results of an experiment in establishing an experimental "health town." Some three years ago the Metropolitan Life Insurance Company donated $100,000 to the National Tuberculosis Society "to show that unnecessary sickness and death, particularly tuberculosis, can be eliminated by medical and nursing care, personal hygiene, and adequate health administration." Framingham, Mass., was chosen as a city suitable for this experiment. A Welfare Committee provided physicians, dentists, and nurses for the schools, baby clinics, domestic science and hygiene instructors, and neighborhood committee. When the movement started Framingham was spending 39 cents per person a year on public health; this has been increased to one dollar per person and another dollar has been added by subscriptions. In 1916, previous to the demonstration, the baby death rate was 81 per 1,000 living births; in 1917, this was lowered to 62. From 1906 to 1916, approximately 14 persons per 1,000 died each year; at the end of the first year of the new regime this number had been reduced to 11. Before the work started 121 persons died annually from tuberculosis; during the first year of the new system the number was 99, the second year 79, and this year 76. Out of a population of 17,000, 12,000 persons have received physical examinations and the remaining 5,000 are being examined and referred to their local physicians. They have found that 70 per cent. of the people are in need of medical or dental advice or treatment. The experiment leads them to the belief that 60 per cent. of the sicknesses could be prevented. The children of Farmingham who are under par are provided with a summer camp and every effort is being made to have them become strong and well.

Cholera in Korea.—A special despatch from Seoul, Korea, to the Associated Press, under date of September 15, states that cholera is widespread in that city and is causing as many as one hundred deaths daily.

Shortening of the Premedical Course Suggested.—The members of the Pennsylvania State Homeopathic Medical Society, at their final session in Philadelphia on September 20, passed a resolution appealing to the National Federation of State Medical Boards to shorten the premedical course so that the degree of M.D. might be obtained after six years' study instead of seven.

Drs. Terry M. Townsend and Julius J. Valentine have removed to the Wellsmore, 2178 Broadway, New York.

Dr. Herman E. Schorr has returned from service in the army and has become assistant physician at the Riverdale Sanitarium, New York City.

Dr. James M. Smith, an American physician employed by the Potosí Mining Company, who was kidnapped by the Mexicans and held for a time for a ransom of $6,000, has been released.

Dr. Joseph B. Howland superintendent of the Peter Bent Brigham Hospital at Roxbury, Mass., was elected president of the American Hospital Association at its annual convention held recently in Cleveland, Ohio.

Dr. Sidney R. Burnap has been appointed associate dean of the College of Physicians and Surgeons of Columbia University. This is the first time the College of Physicians and Surgeons has had an associate dean.

Correspondence.

LIQUOR LICENSES FOR PHYSICIANS.

To the Editor of the Medical Record:

Sir:—The 150,000 physicians of the country should protest against the clause of the Prohibition Enforcement Law, now before Congress, which compels them to take out a "permit" to prescribe alcoholic beverages in quantities not to exceed an arbitrary limit laid down by a lay body. Already physicians are compelled to take out a Federal and a State license to prescribe opium and its derivatives. This is obligatory under an act passed mainly to control the sale and distribution of narcotic drugs after these were used as a substitute for the alcoholic beverages denied the negroes of the South under the prohibition laws originating in that section of the country.

If Congress can limit the use of alcoholic beverages to sacramental and medicinal purposes, it should be competent to punish all offenses against such enactments without passing an oppressive license law affecting the whole medical profession. Inasmuch as clergymen do not have to take out a permit, it might be presumed that physicians would receive the same consideration. This perhaps would be the case were it not for the fact that the Anti-Saloon League estimates every physician as a potential "boot-legger," a conclusion shared evidently by Congress in compelling them to be licensed and supervised by the Department of Internal Revenue.

The Anti-Saloon League also claimed that the "American home" would be converted into a speakeasy unless forcible entry and search were permitted without the formality of a warrant. Congress refused to enact any such measure of prohibition enforcement. The imputation is equally false that all members of a profession elsewhere recognized by their governments as not only an honorable but an honored one will have to be licensed, like the liquor dealer that was, to prevent them from carrying on the trade of "boot-legging" in the United States of America.

John P. Davin, M. D.

117 West Seventy-sixth Street, New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Aug. 25, 1919.

Tuberculous Soldiers.—The report has been issued recently of the Inter-Departmental Committee appointed April last by the Minister of Health and the Minister of Pensions, "to consider and report upon the immediate practical steps which should be taken for the provision of residential treatment of discharged soldiers and sailors suffering from tuberculosis and for their reintroduction into employment, especially on the land."

The main features of the report are that in round numbers the ex-service men suffering from tuberculosis attributable to or aggravated by conditions of service are 35,000. Of these, 22,000 have received or are now receiving residential treatment. There are about 4,000 men at present undergoing residential treatment. The committee finds that there is a serious lack of accommodation in existing sanatoria and hospitals for the treatment of tuberculosis. The number of beds available in the United Kingdom for the male adult population is between 10,000 and 11,000. The provision of army hutments will not solve the problem, although it is possible that the best army hospital huts, and others of similar construction would make satisfactory sanatoria, at any rate, for temporary use.

With regard to treatment the committee is of the opinion that it should take place in three stages. First, should come the sanatorium where treatment is mainly emphasized; next the colony where treatment is continued, but where training is the main objective; thirdly, the permanent village settlement, where permanent employment is afforded, always under medical supervision. The training colony should merge into the permanent village settlement as the sanatorium does into the training colony. They must, therefore, be correlated, and in addition there are great advantages in their being in the same geographical area, for then a patient can easily pass from one stage to another without having to make a new plunge into unknown surroundings.

From the financial point of view, it is with respect to the permanent village settlements that the committee makes their chief recommendations. It is suggested by the committee that the Government should at once make provision in the estimates for £1,000,000 to be used for the purpose of financing the cost of a number of village settlements, primarily for ex-service men. After insisting upon the superiority of sanatorium over home treatment for advanced cases, the committee strongly urges local authorities and large employers of labor to use every effort to help in solving the difficulty by giving special facilities for the employment, under the best possible conditions, of ex-service men who feel unable to take up life in a village settlement

The fact must be taken into account that the treatment of tuberculosis in Great Britain is still voluntary, and the committee was unable to consider the cases of ex-service men independently of that of the civilian population generally. Like civilians, ex-soldiers are often unwilling to submit to treatment for a sufficient length of time. It is true that the difficulty might have been overcome by refusing to discharge tuberculous soldiers until they had passed as medically fit. However, the committee refused to make use of the military machine for this purpose. The accommodation for and means of treatment of tuberculous soldiers are lamentably insufficient and the idea of making use of the old expedient of exporting such persons to the sparsely populated areas of the Empire cannot be entertained. Imperial Free Trade does not go the length of free trade in disease and the Dominions are quite within their rights in rigidly excluding those of the motherland afflicted with tuberculosis. Consequently, the British consumptives must be treated in Great Britain. Experience seems to show that a considerable proportion of consumptives can be rendered self-supporting and the suggestions of the committee are in line with up-to-date medical practice.

Facial Reconstruction.—The weapons of destruction used in the past war, and especially the high explosives, did an immense amount of damage to the heads and faces of those on the firing line. In consequence, the question of repairing these injuries as far as possible has been one of grave import. From all points of view the reparation of face injuries is a very important phase, perhaps the most important phase of surgery. Up to the time of the war not much had been done in this direction in this country. More progress probably had been made in America. However, the war rendered it necessary that English surgeons should busy themselves with working out practical plans for reconstructing damaged faces. Sir Arbuthnot Lane was one of the first to suggest a scheme whereby this form of surgery could be practised effectively. Owing to his energy and initiative, and to the earnest collaboration of some younger men, foremost among these being Major A. R. Gillies, R. A. M. C., the hospital at Frognal, Sidcup, was established. To Major Gillies is due the honor for the evolution and development of this really remarkable institution. He was the pioneer, the designer of the buildings and the deviser of many of the wonderful methods for restoring the mutilated human face to the similitude of its previous appearance. A full description of the hospital at Sidcup would take far more space than the editor can spare for a letter. It may be said that no better situation for such a hospital could have been selected. It is within easy distance of London, in a lovely picturesque country. The estate on which it is placed belonged to an old family and the mansion is used as a home for the medical staff. The grounds are particularly beautiful, with tennis courts, lawns for bowling, and for other country games. There are several magnificent trees, among them being the second largest oak tree in Great Britain. But, of course, it is in the hospital itself and in the patients that the chief interest centers. While, as said before, prior to the war not a great deal had been done in England so far as face reconstruction was concerned, so much progress has been made that at the present time this country is second to none in this branch of surgery. In the early part of the war Major Gillies began at Frognal in a very

modest way, one comparatively small building being in use. From that nucleus one, if not the largest hospital for face injuries has been established, a hospital complete in almost every detail. The buildings are of one story, made for the most part of wood, iron and glass, and erected in the shape of a semicircle. They include wards, operating rooms, dental department and the necessary offices. A considerable part of the success of the treatment at Frognal is owing to the close cooperation between Major Gillies and his staff and the dental department, the head of which is Captain Fry. To the originality and ingenuity of Major Gillies is owing most of the positively brilliant results which have been obtained by treatment at Frognal. He carefully considers each case, and works out methods which are best adapted to be of practical value and at the same time to remedy as far as possible facial deformities and blemishes. For instance, he has employed double-bridge flaps brought down from the scalp to replace lost skin over the chin. He has also inserted large osteocartilaginous grafts from the seventh rib, thereby establishing power of mastication where previously there had been none. The hospital at Frognal, Sidcup, supplies triumphant testimony to the modern surgical skill and is a monument to the infinite resource of its guiding spirit, Major Gillies.

Vivisection in Great Britain in 1918.—The number of experiments on living animals performed in 1918, according to a home office statement, issued recently, was 77,610, or 22,068 more than in 1917. Experiments with anesthetics numbered 1,557; the remainder, inoculations and hypodermic injections, were done without anesthetics, Home office inspectors who witnessed a large number of the experiments found the animals suitably lodged and well cared for. The irregularities reported were neither numerous nor serious. They all occurred unknowingly; generally from misunderstanding.

Smallpox in England.—It was stated recently in the House of Commons that during the month of July and the first week of August 60 cases of smallpox had come to the knowledge of the Ministry of Health. Of these one group of cases numbering 25 up to August 7, was associated with the return home of a soldier.

Death of Professor Augustus George Vernon Harcourt.—This distinguished chemist died on August 16, 1919, in his 85th year. He was a pioneer of physical chemistry but remained to the end of his life a sceptic toward the new theories of solution and ionization. His discoveries were numerous and he was president of the Chemical Society of Great Britain in 1895.

Progress of Medical Science.

2. **The Emotions and Their Mechanism in Warfare.**—Tom A. Williams says that it has been alleged that the emotional strain of the war is the direct cause of many functional disturbances of long duration seen in the soldiery. He finds strong reasons against this interpretation. In the first place, the number of men showing emotional perturbations, apart from those having organic diseases or definite toxic conditions, is comparatively small as shown by figures from various army centers. It has also been contended that most of the cases of emotional disturbances are undetected in the army centers and the patients are evacuated to the interior; here again figures show the contrary. All the figures show that the relative number of emotional cases compared with those definitely hysterical in nature and rapidly curable is very small. Furthermore, patients of the emotional type, such as those who have been called psychasthenics, are able to remain in the firing line without greater inconvenience than they would suffer in civil life. Indeed, they do not break down until they are given responsibilities too great for them to bear. In really extreme fear physical signs such as pallor of the face, changes in the pulse, sweating, pilomotor reactions, and pollakiuria, are always present. Tremor, when it occurs, does not possess any characters which enable one to distinguish it from an assumed tremor, and is a very poor ground upon which to make a diagnosis. Tachycardia is not a diagnostic criterion, because tachycardia is often developed in many patients who are not at all in a state of fear, but as a result of cardiac exhaustion, intoxication, or disorder of the thyroid gland, none of which may have anything to do with the emotions as regards their origin. When anxiety states are genuine they must be completely differentiated from asthenic conditions. The real mechanism is an associational fear psychosis. The importance of the distinction in practice is that such cases are readily curable but only by proper psychotherapy, whereby it is perfectly useless to attempt to cure by psychic means symptoms which are the result of asthenia, whether constitutional or acquired. Among these patients there are two distinct types namely, (1) those who are simply fatigued, and in whom in consequence the power of inhibition has been lowered, and (2) those in whom there is no question of exhaustion—the psychogenetic cases. The real mechanism of this latter type is the conditioning of the mental attitude by a belief that they are no longer capable of withstanding what they have learned to believe (by suggestion) is the exceptional psychic strain of life at the front. It is this vicious mental attitude which has to be changed in order to cure the condition. This can be done in a comparatively short time by a proper understanding of the patient and a reconditioning of his reactions toward the situations which have hitherto provoked dread. In cases which the writer cites this has been done by finding out the circumstances which induced the first symptoms and then reconditioning the patient's reactions by compelling him or her to explain them in writing, by persuasion of the most impersonal, indirect kind, and finally by psychomotor exercises directed toward overcoming the patient's particular difficulty. Thus the patient learns to see in what way his reactions have occurred, and is thereby enabled to forestall them. This must not be done by cowardly avoidance of the situations which provoke the phobia, but by facing them with a clear and open mind and analyzing his own relationship to the situation each time it arises. In this way the situation becomes shorn of its emotional aspect, for the patient has learned to view it scientifically, whereupon the morbid effect ceases. This method is essentially different from the former methods in which these patients were treated, such as emphasizing the lack of gravity of the phobia, ridiculing it, or worse still, attempting to distract the patient in occupations, recreations, or worse of all, by hypnotism, isolation, or rest cures. Williams states that collective suggestion is a most important factor in maintaining high courage in troops. This, of course, depends upon the officers. However, men who enter the neurological services on account of bombardment hysteria do so in the main because the craveness of the individual has overpowered the influence of the collective morale. The important business of the neurologist is to be able to demonstrate to such men that the excuse in which they believe is

not legitimate, that they are not suffering from a physical disorder of the nerves, but are mistaken with reference to the real motivation of their illness. On the other hand, it must not be forgotten that in very many men whose morale flinches, it does so because of a reduction of the resiliency of the organism.

4. Recurrences After Operations for Empyema.—Franklin A. Stevens states that he has been in the fortunate position of being able to complete the records of 123 cases of empyema, observed first by the Empyema Commission at Camp Lee, Va., and subsequently at General Hospital No. 12 at Biltmore, N. C. All of these patients were admitted during the first six months of 1918, and as far as results are concerned, permit a comparison between the treatment of empyema by simple drainage combined with the Carrel-Dakin method. The first group consists of 100 cases which had been treated by simple drainage immediately following diagnosis, and includes the cases up to the middle of April, 1918. Under this treatment 56 patients were healed; the empyema in the remaining 44 became obstinately and persistently chronic until treated by the Carrel-Dakin method. In only 10 cases was a thoracoplasty of moderate extent finally indicated. In the second group there were 23 patients who were admitted during April and May of 1918. They were treated by preliminary aspiration until the primary infection of the lung had subsided, and subsequently by thoracotomy and surgical solution of chlorinated soda. Among the cases healed under simple drainage 14 or 25 per cent. of the recurrences were encountered within eight months after the primary healing. The majority of these were discovered during the first or second months. Ten of these cases, occurring at the site of the primary operation, were caused by hemolytic streptococcus, the organism which was the cause of the original infection. Among the 67 cases healed under the Carrel-Dakin treatment, comprising the refractory empyemas of the earliest group as well as those in which surgical solution of chlorinated soda had been used throughout, there were eight recurrences. A study of these recurrences is an interesting demonstration of the efficacy of the Carrel-Dakin treatment. The group thus treated not only shows a higher percentage of perfect results, but also that the pus pockets which were discovered were usually at some distance from the original focus. In discovering these secondary foci there were two symptoms which proved of the greatest value: 1. The patients either never regained their normal weight or even lost weight in spite of the fact that they were continuously kept in high carbohydrate diet. 2. In all cases of recurrence of a purulent nature, the pulse rate was always rapid and there was also a moderate fever. The final results of the treatment of empyema, the writer says, can be ascertained only after the lapse of a considerable period. This period is of variable length and depends on the particular organism causing the infection, on the size and shape of the cavity, and on the particular method of treatment adopted. Recurrences are more common when an empyema is allowed to close while the cavity containing air still exists. In recurrences, small collections of fluid in the chest gave physical findings which varied according to their location, the most constant physical finding being impairment of the percussion note. Other abnormal physical signs are described and the point emphasized that in order to determine definitely the cause of such signs it is preferable to study them carefully in conjunction with stereoscopic plates, before diagnostic aspiration is attempted. The treatment of recurrences depends entirely upon the character of the fluid found. When it was clear and sterile, aspiration was all that the case required. Cases which have shown a recurrence at the site of the primary operation frequently have recurred again in spite of the greatest care exercised in treating them; in many of these cases of second recurrence there were small pieces of necrotic bone in the sinuses.

3. The Antiscorbutic and Growth-Promoting Value of Canned Vegetables.—Mabel E. D. Campbell and Harriette Chick describe this work which was undertaken at the request of the Controller of Horticulture of the Food Production Department. The experiments consisted essentially in estimating and comparing the minimal amounts of these vegetables—(a) when raw, and (b) after canning—which must be added daily to a basal scurvy-producing diet in order to protect young guinea-pig from scurvy over a period of three months. It was found that in the process of canning vegetables the greater part of the original antiscurvy value of the raw vegetable is destroyed. In the case of runner bean pods the loss is estimated at 90 per cent. of the original value; in the case of cabbage at about 70 per cent. of the original value. The process of canning cabbage included heating in water for about an hour at 90 deg. to 100 deg. C., and for beans the process was repeated on the day following. This loss is primarily due to the destruction of antiscurvy material occurring during the heating involved in the process of canning. A further loss may be expected to take place during the period of storage. The canned cabbage was examined two weeks after preparation and the canned beans three months after. In the case of green-leaf vegetables which possess, in addition to the antiscurvy vitamine, the "fat-soluble" growth-promoting accessory factor, the latter substance is also lacking in the canned material unless the liquor be also taken. The value of canned vegetables as regard antiscurvy and growth-promoting properties must be regarded as negligible. An investigation into the "Antiscorbutic Value of Some Indian Dried Fruits," by Harriette Chick, E. Margaret Hume, and Ruth F. Skelton showed that dry tamarind, cocum, and mango possess a definite but small antiscorbutic value. This value is greatly inferior to that of raw cabbages, turnips, germinated pulses, orange juice, lemon juice, but equal or superior to that of carrots, beet roots, cooked potatoes, raw meat juice, reckoned weight for weight in natural condition. A comparison between the "Antiscorbutic Properties of Fresh, Heated, and Dried Cow's Milk," by Rosamund E. Barnes and E. Margaret Hume, determined by means of quantitative nutritional experiments with guinea pigs and monkeys, showed that cow's milk, even when fresh, was a foodstuff comparatively poor in antiscorbutic properties, and large daily rations, 100 to 150 c.c. daily for guinea-pigs and 125 to 175 c.c. daily for monkeys were needed to protect these animals from scurvy, when upon a diet otherwise devoid of antiscorbutic material. Dried milk was found inferior to raw milk in this respect. Even with material of quite recent manufacture the writers were unable to protect guinea-pigs from scurvy

with any amounts that it was found possible to administer. In case of monkeys the minimum protective dose was found to be approximately from 250 to 300 c.c. daily; in other words, about half the original antiscorbutic value of the fresh milk had been destroyed in the process of drying. "Scalded" milk was found distinctly superior to dried milk. These facts form a strong argument for the desirability of adding an extra antiscorbutic to the diet of infants nourished on dried milk. The most suitable substances for this purpose are raw orange juice, raw turnip juice, or juice of tomatoes, raw or canned. Grape juice and carrot juice are also useful but less valuable. Potatoes cooked and mashed can be employed in cases in which starchy foods are not considered unsuitable. Some evidence was obtained showing that winter milk is inferior to summer milk in antiscorbutic properties, corresponding to the difference in the cow's diet at these different seasons. In this connection the suggestion is made that the value of winter milk in this respect might be raised if turnips were employed in winter feeding in place of mangolds, where possible. No significant difference was detected in the growth-promoting properties of raw and dried milk respectively, and this was true of both guinea-pigs and monkeys. In both cases growth declined with the onset of scurvy symptoms, but until this occurred the growth made upon the diets containing dried milk was equal to that obtaining when equal rations of fresh milk were substituted.

1. An Address on Some Applications of Experience Gained by the War to the Problems of Civil Medical Practice.—Sir. William Hale-White states that in some medical diseases the experiences of the war will be of great value. He says that the war has increased our knowledge of organic valvular disease of the heart, but, thanks to T. Lewis and his coworkers, it has been more widely diffused. The chief applications of war experience to civil work, so far as the heart is concerned, are: The heart must be judged by the work it can do; it is the duty of the doctor to determine this and to advise accordingly. Many systolic murmurs do not indicate organic disease; proper care must be taken before diagnosing a dilated heart. The commonest irregularities of the pulse are of no pathological significance. To tell a patient his heart is weak, dilated, or diseased, when it is not, may cause him harm. Several problems concerning injuries to the pleura and lungs have been of great interest, but such injuries are rare in civil practice. The war experience of hemothorax has emphasized the necessity of draining the pleural cavity if the fluid effused is not sterile and the tendency is now rightly to withdraw the fluid, even if sterile, unless the quantity probably is under ten ounces. The object in pleuritic effusion is to get the lung back to normal as soon as possible, therefore, breathing exercises should be begun early, usually directly after the fluid is taken out; when an empyema has been opened these exercises have the additional advantage of aiding the drainage of the pleural cavity. If the fluid is infected, whether or not it is purulent, the chest must at once be opened. No empyema ought ever to be allowed to become large, and an Estlander operation ought never to be needed. The writer states that few things in his war work have struck him more than the mistakes that have been made about epilepsy. The epilepic has proved a difficult recruiting problem and he has also been found particularly unfit to withstand the nervous stress of war. In the examination of recruits *petit mal* is much more likely to be overlooked than *grand mal*, and its attacks are at times either entirely overlooked or ascribed to a weak heart. The lesson for civil practice that the army experience has taught is that we should be more on the outlook for epilepsy. To fail to recognize it is unfortunate, for not only under such circumstances do we fail to give the proper medicine, but we do not advise a suitable occupation, and many occupations are unsuited for epileptics. In discussing the lessons taught by the war in regard to neurasthenia, the writer states that the neurasthenia of the civilian is the same as that of the soldier, but less severe; he cannot concentrate, his brain will not work, he forgets, loses interest, and later on his sleep; he becomes dyspeptic and thin. Hard work during the war caused many serious cases of neurasthenia among civilians. The war ought to have made all doctors more interested in neurasthenia than some of them have been. Neurasthenic and hysterical patients are, at least, as entrancing a study as those suffering from serious organic disease, and have the great advantage of being capable of cure, yet many doctors will not occupy themselves nearly so much as with those afflicted with, say, malignant endocarditis or cancer of the liver. The war has also taught that we should give our best attention to hysteria. This disease is rare in civil life among men, although since the war there have been many cases among soldiers. These cases lend no support to the sexual hypothesis of hyteria fashionable before the war, and most are agreed that they can be explained best either by the hypothesis that hysteria is due to suggestion or that in the hysteric the supraliminal consciousness is, in part, dormant, and it may be that both suppositions are correct. The war has reminded us that traumatism may lead to hysteria. For the successful treatment of hysteria, the patient's general health must be improved, the treatment must be begun as early as possible, and the doctor must be most careful to avoid, by his mode of examination and by his wording of questions, suggesting symptoms. The war has certainly shown that we should give our best attention to hysteria, that it is very common, and that it is capable of cure. It is well to remember Sir James Paget's famous saying: 'The patient says she cannot, the friends say she will not, the doctor says she cannot will."

8. The Psychology of Prognosis. Thomas W. Edgar.

1. The Usefulness of Headaches.—A. W. Herr emphasizes the point that headache is never a disease, but always a symptom. It is a red flag hung out as a sign that some organ is not functionating normally. Headaches may be divided as to causes as follows: 1. The hemic causes, such as anemia, congestion, and blood dyscrasias, as gout, rheumatism, diabetes, and fevers. 2. The toxic causes, as lead, alcohol, or tobacco. 3. Nervous states, as epilepsy, neurasthenia, and hysteria. 4. Reflex causes, as syphilis or meningitis. So far as location in the head is concerned, headaches are divided into frontal, occipital, parietal, temporal, vertical, and diffuse. The pain of the headache is: 1. Pulsating and throbbing, as in migrain. 2. Dull, heavy, and splitting, as in the toxic or dyspeptic. 3. Squeezing and pressing, as in the neurotic. 4. Hot, burning, and sore, as in the rheumatic and anemic. 5. Sharp and boring, as in hysteria and epilepsy. (Dana.) The first aid to the headache invalid is to remove the cause. If due to eyestrain, go to an oculist and get correction of vision. In a migrain or sick headache, a lavage of the stomach will afford timely relief, but there must be a correction of the dilatation of the stomach, which invariably accompanies chronic cases of migrain. This will require the aid of the sinusoidal current to correct the muscular deficiency of the stomach. If it be a toxic headache most likely the colon will be the

organ at fault. Putrefactive changes taking place here will most readily poison the system and irritate the nerve. Bacteria may increase until they amount to 40 per cent. per volume of the feces. By means of lactic acid ferment (live Bulgarian culture) and a careful and correct dietary this volume may be lowered to two per cent. First aid to a toxic headache is a clearing out of the bowels by means of a high enema, and we may bring to our aid cold neck and head compresses, the use of the sinusoidal current, and massage applied to the head or neck. The patient should be placed on an antitoxic and laxative diet. Reflex headaches are the most persistent and aggravating, and it is here that we find the greatest difficulty in diagnosing the real cause of the trouble. After excluding all toxic and organic causes we are forced to the conclusion that a headache is reflex. We then ask, "Is it from the uterus and its appendages, the stomach, bowels or kidneys, or is it from some source in the head itself, as ear, nose, throat, teeth, or eye?" By exclusion and by knowing the nature of the pain and its location in the head we may determine its source. Pelvic disorders usually give the pain in the occiput or vertex of the head. Headaches from indigestion are usually frontal. Nasal headaches are usually over the eye or at the root of the nose, and if located in the antrum or sinuses are usually unilateral. If from the tonsils or adenoids, the headache is usually diffuse. The teeth produce a one-sided neuralgic headache. The eye is usually the cause of most reflex headaches. From the fact that eyestrain as well as dilated stomach will produce sick headache, in every such case it is well, the author states, to test the eyes as a means of exclusion before proceeding with the treatment of the stomach symptoms.

4. The Value of the "No Good"-Plication of the Cecum.—Douglas H. Stewart likens the cecum to a swill-bucket fashioned with its hoops inside, but with its staves attached to the outside of those hoops and says that by also imagining the aforesaid swill-pail as possessing a lining of some elastic material one can easily construct for himself a working scheme demonstrating the anatomical conditions involved. If the reader will imagine such a bucket subjected to an internal pressure brought to bear upon elastic animal tissues he will see that the staves will spread apart without, and the elastic lining will bulge between the staves whereever it is unrestrained by the hoops themselves. After discussing the causes that favor distension, impairment and atony of the caput-coli, the writer describes his method of plicating the cecum. He states that one cannot determine readily from sight alone whether plication is or is not indicated. By touch he may do so at once; because he becomes aware that there are spots or areas in the colon wall that are akin to internal hernias. If he covers such spots by drawing the longitudinal bands or fibers closer together, then all will be well, whereas if this be not done, the patient never will be well, but will join the large ranks of autotoxemics.

In order that the bands may remain together after being stitched, it is necessary to paint a little of a three per cent. tincture of iodine upon the surfaces that are to adhere and that are to remain permanently adherent, or else, with a piece of gauze to rub a little brush burn, as it were, upon the colonic wall. In either case the stitches are to be introduced in such a manner that the iodine streak of the friction streaking shall be covered by the infolding that occurs when those stitches are properly placed and knotted. Stitches, whether single or knotted, should never cross any tinea. This will make certain that no stitch runs more than one-third of the way around the circumference of the colon, and it makes strangulation impossible or other possible untoward results negligible. Care should also be taken that each stitch is inserted into a tinea, slightly into the circular muscles between the lines, and into the neighboring tinea. When such a stitch is drawn sufficiently tight to make a bulge or pseudo-hernia disappear, then the tension is exactly correct. In a patient complaining that he or she has been operated on for appendicitis and has experienced little or no relief, it may be well if the attending surgeon cleverly narrows the caliber of that patient's swill-barrel.

Revue Médicale de la Suisse Romande.

May 20, 1919

Encephalitis Lethargica.—Cramer writes of this subject and traces the disease backward without difficulty to 1712, when it was known as the sleeping sickness. In 1890 it was known as nona (some use the term noma), grippal coma, grippal hypnosis. To-day we term it encephalitis lethargica. In 1712 Camerarius described the Tübingen epidemic under the term sleeping sickness, and those who read the account to-day can readily comprehend that it agrees in essentials with the malady of 1890 and 1917-19. Between 1712 and 1890 there is little to be found in literature on the subject. The epidemic of 1890 was associated with untreated grippe, as a sequela which is largely preventable. Some victims suggested men in alcoholic debauch. The reappearance of the disease one year before the pandemic of 1918 tends to invert the belief that it came in the wake of influenza. In addition it was transmissible to the monkey, which it destroyed in 48 hours. We now know that it both preceded and followed the latest pandemic of grippe. In Vienna, where a new epidemic of the encephalitis began in 1917, the disease occurred only in the cold months when considerable local grippe was also flourishing. In addition the two affections have points in common, as hemorrhagic diathesis and purulent rhinopharyngitis. In the same number of the *Revue* occurs the brief account of a case of lethargic poliencephalitis, which is none other than encephalitis lethargica under a new designation. The patient, a man of 44, had been through a grippe of atypical course. He was smitten with the lethargic complication while convalescing from the latter. He slept most of the time for three weeks, but made a good recovery.

La Presse Médicale.

July 24, 1919.

Noma Following Grippe.—Portmann reports a unique case of this affection with an illustration. The patient, a man of forty-three, was convalescing from grippal bronchopneumonia and when about to receive his discharge complained of a soreness at the internal aspect of the right buccal commissure. The surrounding tissues were all sound, although the affected spot was seen to be gangrenous and was promptly excised. This act seems to have been in vain, for the entire wound surface soon became gangrenous in turn and the diseased surface began to increase. A second excision was now carried out with the same result as before—the exposed surface quickly sphacelated and the necrosis again extended. A third excision was now performed and a biopsy made. The author now saw the patient for the first time. Although the gangrenous odor so characteristic of noma is nowhere mentioned, the condition as described otherwise seems typical of that lesion.

There was extensive loss of substance involving both the cutaneous and mucous surfaces of the cheek and the adjacent gum. The face was swollen, but in spite of his condition the patient could converse and swallow his food. He had been free from pain from the start and there had been but little fever. There was marked retromaxillary adenopathy. A fourth excision was performed with the thermocautery and deep igni punctures added along with sublimate applications, and the process was arrested. Superficial sloughs then separated or were detached. The author criticises his own diagnosis, for he states that noma is primarily a disease of childhood and of cachectic subjects, while this case occurred in an adult in good condition despite the grippe.

Noma is not necessarily an autonomous condition, however, and given the coincidence of a port of entry and certain kinds of bacteria a focus of necrosis could conceivably result. We know nothing of the bacteriology of noma, and the findings in this case were evidently inconclusive, for a mixture of streptococci, staphylococci, and pneumococci was present. There is no mention of cultural or inoculation experiments.

Book Reviews.

THE REALITIES OF MODERN SCIENCE. An Introduction for the General Reader. By JOHN MILLS, Research Laboratories, Western Electric Company, Inc.; Member American Physical Society; Author of "Radio Communication," etc. Price $2.50. New York: The Macmillan Company, 1919.

THIS is one of the books, of which there cannot be too many, the aim of which is to give to the general reader such information as he needs regarding the recent advances in physical service, which his work in other fields has prevented him from following. Among the subjects treated of are the molecular composition of matter, the electron, energy, force, motion, and electrolytic dissonation. The book is not for the kindergarten, for the author presupposes a certain knowledge of the elements of science in his reader, and the latter must give also attention if he would get the knowledge he seeks. If he is willing, however, to read the book with care he will find it a treasure house of knowledge of fascinating interest and he will be amply rewarded for his pains. The work should appeal forcibly to the physician who has neither the time nor the preliminary training for the study of text-books of physical chemistry, but who must, as a member of a learned profession, have a certain understanding of a branch of science which touches his own at many points.

THE INTERNAL SECRETIONS AND THE NERVOUS SYSTEM. By Dr. M. LAIGNEL-LAVASTINE, Paris. Authorized Translation by Dr. F. T. ROBESON, New York. Nervous and Mental Disease Monograph Series, No. 30. Price, 75 cents. New York and Washington: Nervous and Mental Disease Publishing Company, 1919.

ONE has only to consider the subject of the internal secretions to realize how very infantile the science of medicine is. With a few striking exceptions, our accurate information concerning these glands is exceedingly meager. And yet the subject is one of vast importance, for there is no branch of medicine in which it does not play a large part. For that reason any addition to our information is most welcome. Professor Laignel-Lavastine's researches have extended over many years and have covered a wide field, and his deductions, therefore, merit respectful attention. It is gratifying to have this translation of his monograph, and his classification of the disturbances of the endocrine system should be of distinct help to the profession.

THE SURGICAL CLINICS OF CHICAGO. Vol. III, No. 1, February, 1919. Published Bi-Monthly. Price per year, paper, $10. Philadelphia and London: W. B. Saunders Company, 1919.

THERE are seventeen contributors to this issue of the Clinics. The first two articles are contributions on war surgery; one by Speed entitled: "Surgical Cases at an A. E. F. Evacuation Hospital," and the other by Besley entitled: "Secondary Hemorrhages as Observed in War Surgery." The rest of the volume is made up of reports of clinical lectures on a great variety of subjects. Among the most interesting and instructive are a lecture by Lespinasse on blood transfusion; Bevan's lecture, covering six clinical cases; Harger's cases of sarcoma, one of the liver and one of the testicle, with description of metastases and autopsy report; and Kolischer and Eisenstaedt's and McKenna's genitourinary cases.

WAR SURGERY OF THE FACE. A Treatise on Plastic Restoration after Facial Injury. By JOHN B. ROBERTS, A.M., M.D., F.A.C.S., Professor of Surgery in the University of Pennsylvania Graduate School of Medicine, Lecturer in the Civilian School of Plastic and Oral Surgery Established in Philadelphia by the Surgeon General, U. S. A. Prepared at the Suggestion of the Subsection on Plastic and Oral Surgery Connected with the Office of the Surgeon General. Pp. 442, with 256 illustrations. New York: William Wood & Company, 1919.

WHILE this book was written as an aid in the solution of war problems in orofacial surgery, it is equally valuable now that the war is over; for there are always cases of disfigurement, from one cause or another, requiring such special treatment as is described in this book and one or more of the various plastic operations for final repair. As Roberts says in his preface, the possibility of correcting a hideous distortion of features or replacing a large section of the human face was realized inadequately until this great European war produced so many mutilations. In this work the author "has endeavored to correlate the results of military and civil practice in traumatic surgery of the face, realizing that the fundamental principles of surgical science hold sway in both provinces."

Roberts considers the various subjects under three general headings: Surgical Anatomy of the Face; Pathology and Treatment of War Wounds of the Face; and Reconstructive Treatment of War Injuries of the Face. Except for the magnitude of some of the injuries, an active surgeon in the field of traumatic surgery will often have to deal with just such cases as are described in this book. Facial injuries from automobile and industrial accidents, falls, blows, burns, etc., may be as septic as any produced in war; and almost everything that is said in regard to handling war injuries in this region is applicable to these. All the subjects are well covered and the author shows his familiarity with the best work that has been done by oral and facial surgeons here and abroad. The chapters on hemorrhage, the principles of plastic repair of wounds, and plastic surgery of the face in general, are among the many which contain numerous valuable suggestions. Unfortunately, the page shows a lack of careful proofreading, though generally the meaning is clear. The book should form a valuable addition to the surgeon's library.

COLLECTED PAPERS OF THE MAYO CLINIC, ROCHESTER, MINNESOTA. Edited by Mrs. M. H. MELLISH Volume X. 1918. Philadelphia and London: W. B. Saunders Company, 1919.

THIS handsome volume consists of more than one thousand pages, and contains about one hundred papers by some fifty contributors. With very few exceptions these papers have all been read before some medical society, and have also been printed in various well known medical journals; hence, their present publication in book form is practically their third appearance, and the volume is really a volume of reprints. The articles cover a wide field, and are classified under the general headings of: Alimentary canal; Urogenital organs; Ductless glands; Heart; Blood; Skin and syphilis; Head, trunk and extremeties; Nerves; Technic; and General. Many of the contributions are of considerable practical value and will appeal to the busy physician and surgeon. Others represent patient research work the results of which may, later on, be found serviceable in diagnosis or treatment. The bill of fare presented in this volume is so varied that the reader who cannot find in it something which appeals to his intellectual appetite must be very hard to please.

THE JOHNS HOPKINS HOSPITAL REPORTS. Volume XVIII. Baltimore: The Johns Hopkins Press, 1919.

THIS volume of reports contains reprints and abstracts of fifty-three papers which appeared in 1914, 1915 and 1916. They cover a wide range of subjects in clinical and experimental medicine and pathology. There are numerous reports of instructive and unusual cases and at the end tables showing the percentage of autopsies obtained in the different services. It may be said that these percentages are enviably large.

THE SURGICAL CLINICS OF CHICAGO. Vol. III, No. 2, April, 1919. Octova of 244 pages with 63 illustrations. Published bi-monthly. Philadelphia and London: W. B. Saunders Company.

FOR variety of subjects and teaching value this is one of the best numbers that has appeared recently; and there are so many clinics worthy of special mention that it is hard to select some for special reference without doing injustice to others. Those that appear to us the most interesting and instructive are the Clinics by Andrews on multiple drilling of oblique fractures; by Brophy and by A. J. Ochsner on harelip and cleft palate; by Carl Beck on syphilis of the stomach; by Carl B. Davis on plastic repair of the deltoid by transplanted fascia lata; by Bevan on various subjects; by McCarty on fractures of the carpal scaphoid; and by Moorhead on prolapse of the uterus in a virgin 18 years of age.

Society Reports.

AMERICAN ORTHOPEDIC ASSOCIATION.

Thirty-Third Annual Meeting, Held at Atlantic City, N. J., June 14, 16, and 17, 1919.

DR. HERBERT P. H. GALLOWAY, OF WINNIPEG, CAN., IN THE CHAIR.

President's Address.—Dr. HERBERT P. H. GALLOWAY said that none of the honors of the medical profession were so much to be coveted as those which came from one's own colleagues, and therefore he was very grateful for the honor of being chosen President of this Association. This meeting more than any others, would arouse a sense of responsibility, occurring as it did, with the lifting of the cloud of war. Pain and sacrifice were ever the price of progress, and the war had been the birth pangs of a larger social order and human progress. The war, moreover, had done more to bring orthopedic surgery to its true inheritance than anything else. They could now view proudly the pinnacle of success to which their specialty had attained. Their work was now in the transition period and they could not afford to lose sight of the difficulties of the changing process. The future depended upon their recognition of, and shouldering of, responsibility. Their branch of surgery divided itself from general surgery in the first place because the general surgeon did not have the patience to study the tiresome, and often neglected cases which required mechanical skill. The boundaries of the specialty were slowly widened and operative surgery came to supplement the process of mechanics which early distinguished the orthopedic regimen. Therefore the orthopedic surgeon had developed a new combination of mechanical principles and operative technic and skill. The experience of the war had shown that many cases, before thought of as belonging to general surgery, were now recognized as being orthopedic. Many of the younger general surgeons during the war had learned the principles of military orthopedic surgery. There would also seem to be danger that some of the orthopedic men might attempt to undertake general surgery. Conscience and individual honesty of the practitioner would be the check to counteract this. The specialist who attempted to handle cases that lay outside of his specialty simply brought discredit on his specialty. Another point to be remembered was that war orthopedic surgery was different from that practised in civil life. Scoliosis, tuberculosis and bone and joint disease needed regular orthopedic skill and mechanical aspect of the specialty was indispensable to their proper treatment. The character of an association must be determined by the individuals of which it was composed. The members of this association must be really representative of modern orthopedic principles. The speaker said he was in sympathy with those who wished to develop themselves, and he had seen raw material develop very well in a few years, but the orthopedic surgeon could not meet the demands laid upon him unless he had wide general training and experience. What one achieved depended upon what one demand of one's circumstances. One found the truth of the words, "Any wage I had asked of life, life would have paid." The *Journal of the American Orthopedic Association* had now been made the official organ of both the American and the British Association. Sir Robert Jones, the Gamaliel of Orthopedic Surgery, was not present, but they were consoled for his absence by the knowledge that it was his loyalty to duties growing out of the war which kept him at home. It was impossible to look into the faces of this assemblage without being painfully reminded of the fact that two of the most respected members would never more be seen in their midst. Dr. G. Gwilym Davis was devoted to his work and died in harness. Dr. Augustus Wilson was to have prepared a brief obituary of Dr. Davis, but, alas! he too fell by the wayside. Both were good men and true. "Their works do follow them."

Dr. J. TORRENCE RUGH of Philadelphia then read the obituary of Dr. G. Gwilym Davis. Dr. ROBERT LOVETT of Boston read the obituary of Dr. H. Augustus Wilson.

Treatment of Ununited Fractures Following War Injuries.—Dr. FREDERICK C. KIDNER, Major M. C., U. S. A., of Detroit, presented this topic. The terms "ununited fracture" and nonunion" were purely relative ones, and much too commonly used. Real nonunion was extremely rare after proper mechanical treatment. Broken bones, if given a chance, persisted in uniting. The term nonunion should not be used until much longer time that was usually conceded had elapsed. It was often the invention of the surgeon who did not give nature's efforts sufficient time to establish solidification. Bone formation depended upon many little understood factors. Delayed union was often seen after many causes, frequently among these meddlesome surgery. This occurred often in civil life, when the surgeon and the patient were in a hurry, and change of treatment was tried to hasten union. In war, the overworked surgeon had to let his patients alone and be content if the apparatus was holding. Long physiological rest was also the fate of the war patient. Delayed union, also might be the result of malnutrition or syphilis or other systemic causes. These causes must be recognized and removed. Other causes were sepsis, and intervention of muscle and fascia between the fragments, this, however, was more common in civil than in military life. In war delayed union or nonunion were most often caused by much loss of bone substance, frequently the result of too enthusiastic débridement on the part of the surgeon who explored the fracture. This ruthless débridement was an unmixed evil. Such treatment required conservative and skilful hands. It was found that even septic and apparently devitalized bone fragments had an uncanny knack of coming to life and acting as bone grafts. In war fractures recurrent sepsis was an ever present menace; even as late as eighteen months after healing of a wound pus pockets had been found in the deep tissues. Operative treatment, then, in delayed union was to be avoided, except as a last resort. Certain essential factors in the prevention of nonunion were, first, and most important, immediate alignment of the fragments by efficient traction applied in the direction of the axis given by muscle pull to the shorter or less easily controlled fragments, the traction being in the line which the shorter fragment naturally takes. Immediate reduction was important within the first hour or two, because less traction was needed to obtain alignment before irritative tonic spasm was set up in the muscles, and also because early blood effusion from the bone fragments contained many osteoblastic elements. By obtaining reduction before this effusion had stopped and coagulated the bone-forming elements were better distributed and arranged to form a plastic callus with resultant prompt union. Good alignment, once obtained, must be maintained for a considerable period of time. Hardly second in importance to early alignment was the retention in place of all possible bone fragments. No fragment should be removed unless it seriously blocked drainage in the depths of the wound. It was not necessary to remove bone fragments to avoid sepsis. If there was any attachment to soft tissue, the fragments would live and produce new bone. Wholly free fragments would often attach themselves and act as grafts. Muscle intervention often proved to be the most difficult cause of delayed union to detect. It should be suspected in cases of excellent alignment where no cause of nonunion could be found, but where union did not take place. Operative removal was necessary. Overcoming of bad position when union had been delayed some time required skill, judgment, and appropriate mechanical means. The application of calipers so as to obtain the best leverage would often bring fresh bone surfaces into contact, and produce union. Overcoming of large gaps in bone by purely mechanical means was often impossible. In gaps of one or one and a half inches sometimes shortening was permissible. With a very long gap, maintenance of good alignment and the exercise of inexhaustible patience would sometimes achieve a result. Nature would do much in the way of autogenous grafting. Often when waiting for the disappearance of sepsis, to do bone graft operation, the *x*-ray would show a delicate line of new bone gradually bridging the gap. The vitality of small bone fragments and islands of periosteum was surprising. Often in large losses of bone, through injury or surgical intervention, one supposed that no osteogenetic function could be left be-

tween the main ends of bone, but the *x*-ray would reveal islands that could have no origin other than the despised fragments. One was forced to conclude that bone, instead of being the least resistant structure to infection, was really one of the most resistant. Massage and similar measures aided in maintaining nutrition of the soft parts and were of undoubted value in promoting union. When all external mechanical devices to overcome delayed union had been exhausted, including the patience of surgeon and patient, there still remained certain true ununited fractures. These cust be treated by open surgery. The choice of various operations was open: metallic ivory, boiled bone plates, pegs, tubes, screws, wire, magnesia, heterogenous and homogenous and autogenous bone grafts, and simple joinery of the refreshed ends, all had their advocates. One had to choose such means as careful, honest, surgical observation of long standing had shown to be consistently successful. One had also to remember that the torn, bruised, septic tissues of the soldier would not stand so much surgical insult as the healthy tissues of the civilian. In civil life there was often enough excess growing bone power to overcome the atrophy caused by bone plate, but this was not true in war fractures. Experience had proved the failure of this method in these cases, and bone plates undoubtedly increased the risk of sepsis. Wiring, metallic bands, and ivory plates, screws, and pegs had the same objections that they acted as foreign bodies and irritants. Operative procedures, then, to procure results must depend on absolute simplicity. The easiest, simplest operations, done in the easiest, simplest way, were the best. In fractures with little loss of substance the removal of scar tissue and ensuring contact of fair-sized bleeding bone surfaces would usually suffice. A catgut or other absorbable loop would steady the ends. Sometimes a simple interlocking joint, made with mallet and chisel, was necessary to secure good contact. With loss of bone substance, the bone transplant was necessary. In large bones with good nutrition almost any type of transplant was successful. In small bones, or in large ones with much damage, the type of graft was important. Where nutrition was poor, too much grooving or insult to the medullary cavity meant failure. The operation of Chutro, that is, cleaning one side of the bone fragments and insertion of a wafer of periosteum and superficial cortex removed from the tibia, between the bone and the periosteum, was the method of choice in such cases. Circulation was easily established in such a transplant and it could survive considerable sepsis. Any and all operations, however, might fail because of septic flare-ups, no matter how long one waited. The two-stage operation would save many disappointments in operation on ununited fractures. At the first stage all scar tissue was removed and the field thoroughly explored. The wound was then closed tightly. If no sepsis appeared, one could reopen and do the bone operation. In cases of sepsis wide drainage was done. The conclusions were: (1) Avoid delayed union by early accurate reduction; (2) wait for very long periods before interfering surgically; (3) when surgery does become necessary, do the simplest possible operation by the two-stage method.

Preventive and Prophylactic Orthopedic Practice.— Capt. CHARLES L. LOWMAN, M.C., U.S.A., of Los Angeles, California, presented this topic. Since 1914 orthopedic surgeons had been dealing largely with war reconstruction work and faulty statics in soldiers. War surgery had emphasized the need of prophylaxis in regard to future function, and numerous cases showed that faulty statics played the chief part in disability. It was seen that about 80 per cent. of soldiers complaining of back symptoms, mostly referred to the lower spine, were of the long-backed type, and the *x*-ray showed various anatomical deviations in the lumbar-sacral region. An enormous number of postural defects were noted, both among the rejected, and among those in service. That these originated during the school age was shown by figures stating that 70 to 85 per cent. of school children had postural defects. Those that broke down in military life merely showed which were the potentially weak. Thus orthopedic had a broad outlook, both as to corrective and preventive work. The corrective or operative side might be more spectacular, but the influence of preventive work on the health and efficiency of the future generation would be important in increasing human happiness and usefulness. The necessity for physical supervision during childhood was therefore of the highest importance. About 50 per cent. of the adult cases seen in the orthopedic surgeon's office were due to functional faults, such as improper alignment and weight bearing, often with other pathology—arthritis, periarthritis, periostitis, with neuritis from such conditions as flat feet, pronated ankles, knock-knees, torsion deformities, etc. Many cases seen of shoulder girdle neuritis could have been prevented during adolescence. Uncorrected bow-leg brings the adult with valgus ankle and flattened feet. Knock-knees are more apt to be noted and corrected earlier. The routine drill of the war manifested the wonderful improvement in health of soldiers who had been corrected of scoliosis and visceroptosis. These lessons could well be applied with advantage to the younger generation. There should not be so much need for reconstruction work in childhood. The work should be constructive and directed to preventing those conditions which tended to lower health and efficiency in later life. The management of this question of physical education and supervision was a large problem. There were many enthusiastic men and women already engaged in physical educational work, but they lacked guidance. One could not therefore continue to leave this responsibility entirely in the hands of educators. If the methods in use did not meet the needs, orthopedic men were the ones to direct changes, and to outline necessary procedures. The most effective and far-reaching work could be done during the grammar school age. Gymnasia were seldom seen for children in this grade, and all the corrective work, if any, was given under supervision of the grade teacher. It should not be too much to demand that a trained physical director, schooled in preventive methods, and competent to recognize potential defects, should be assigned to each school, to act in advisory capacity for both teachers and parents in regard to children needing correction. Supervision of games was an important phase of the work, and such activities as folk dancing, rope jumping could be used correctively. Most of the groups could be divided into those showing obvious defects, like pronated ankles, flat feet, knock-knees, round shoulders, round or hollow backs, unlevel hips. These defects could be detected by, say, a quarterly examination, when new pupils could be lined up and the examiner could note unlevel shoulders, tilted pelves, state of scapulæ, back, knees, ankles, and feet. Faults in foot alignment were easily noted in gymnasium slippers. Upon assembling this data it would be found that many children registered two or more defects. These should have immediate attention, and a more detailed examination later. This method would result in recognition of the more obvious defects, and early prophylaxis could be instituted.

Experiences with Astragalectomy. — Prof. PIETRO CHUTRO of Buenos Aires presented this subject by invitation. The treatment of Willems had been found admirable where there was no grave fracture of one of the important bones of the articulation. It should be pointed out that the astragalus was so exactly adapted to the mortise that, except in certain fracture by rifle-ball, any fracture of this bone gave rise to deformity which rendered joint movement difficult. Often, when several joint elements had suffered injury, the cartilage, the bone fragments, and the synovial membrane contributed to retention of pus. The liability of infection of neighboring tendon sheaths also would indicate that astragalectomy should be instituted from the first, in order to properly drain the ankle-joint. This result, however, was not always accomplished. The immediate infection appeared to subside, but after some weeks the foot remained swollen, the wound bled easily and showed much granulation. Movement became impossible from pain and mechanical hindrance. The foot tended to remain swollen, the toes immobile and contracted, the sole convex, a tactile hypersensibility persisted, and the foot was entirely useless. Under these conditions amputation seemed necessary, which, in the great majority of cases, could have been avoided earlier. In inquiring into the reason of these difficulties, it would seem that infection alone was not enough to account for them, because after astragalectomy there

was drainage under conditions. The following explanation was therefore proposed: After astragalectomy the foot was immobilized at a right angle in an appliance that was not conformed to the inferior part of the leg, and posterior half of the foot. It only served to give a bearing point to the heel. Thus the bones of the leg dropped backward; the mortise, no longer retained in place by ligaments, was applied to the nonarticular surface of the os calcis, and the whole foot underwent dislocation forward. The consequences of such displacement were: (1) Disappearance of the retromalleolar spaces, the tendon of Achilles coming nearer to the leg bones; (2) the backward displacement of the mortise border caused flexor contracture of the toes, and plantar flexion of the fore part of the foot, with marked equinus deformity; (3) the tension of the mortise on the tendons acted on the posterior vasculonervous bundles; circulator embarrassment was enhanced by compression of the vessels, the return circulation suffering especially, resulting in passive hyperemia, cyanosis, sweating, and variations in local temperature; (4) the change in the contact of the mortise forced the os calcis into a completely horizontal position, instead of its normal elevation of from 11 to 19 degrees. These lesions were still further aggravated by lateral displacements at the level of the ankle, the contraction of the tendon of Achilles tending to become accentuated. The deformity became very difficult to correct, after having persisted for some time. Sometimes after tenotomy of the Achilles tendon the foot could be brought back to a suitable position. An ultimate treatment of massage, hot air and active mobilization and reeducation might complete the cure. In other cases orthopedic amputation might be counseled. In order to prevent this unpleasant train of results certain operative technique was undertaken, outlined as follows: the wounds of entrance and exit were cleaned, and incision was then performed in the form of an italic "s", commencing above the external malleolus, and descending along the anterior aspect of the malleolus to the line of the ankle joint, becoming then almost transverse as far as the prominence of the tendon of the tibialis anticus, then becoming again longitudinal and descending 2 or 3 cm. Astragalectomy was then done and the foot fixed in good position. To fix the foot: a bronze wire passed through the skin and soft parts of the inferior lip of the wound, grazing the posterior-superior border of the cuboid, then following a recurrent path traversing the anterior border of the external malleolus and soft parts of the other lip of the wound. The drainage tubes were placed; the wire twisted. Enough opening remained to allow of free drainage. If the infection had spread to the sheaths of the postero-internal tendons, débridement was done, extending to the joint. The advantages of this fixation were the following: (1) The cuboid was brought close to the external malleolus; (2) the tarsus was projected backward; (3) the anterior portion of the os calcis retained its normal elevation, above the horizontal plane, and flat foot was avoided; (4) the retromalleolar spaces were deeper than normal; (5) there was no traction on the posterior tendons or compression of the vessels; (6) the Achilles tendon was not shortened, and there was less danger of equinus deformity; (7) the concave mortise rested above the articular surface of the os calcis, also concave, there remaining between the two a cavity which would become filled with fibrous tissue, permitting eventually some motion of the foot; (8) the anterior tendons having their insertions nearer together, would gain in force and prevent equinus. On terminating the operation the foot was immobilized at right angles by a figure-of-eight bandage, extending from the heads of the metatarsals to the inferior quarter of the leg. Over this bandage was added a second pad of cotton, and then a new bandage, thus obtaining complete immobilization. Dressings were renewed every fifteen or twenty days. The patient commenced to walk in the fourth or fifth week, without a crutch, leaning on the arm of a comrade, and in a few days he walked alone. Walking could be begun before complete healing of the wound. The results were satisfactory, the shortening was slight, and soon the patient walked without limping.

Osteomyelitis of the Tibia and Ankle.—Prof. PIETRO CHUTRO also presented a short talk on this topic. Osteomyelitis of the leg was different from that of the sinus. It was localized by a thrombosed necrotic congestion. There was formation of pus which would seek exit by the marrow. Pain was caused by the distention. The periosteum must be opened to prevent necrosis, or there would be loss of bone substance which formed a cavity. Before they were doing empirical operations, but lately they had begun to go back to physiology and pathology. With the filling of the cavity the sinus disappeared. The cavities varied with the type of bone. In the tibia there was little variation in the cavities. In bullet wounds with oblique fracture there was never an entire consolidation of the fracture. The bone consolidated on the exterior part. Often the traction of the muscles was so strong that the fracture would not consolidate. Callus was apt to form, particularly about the periosteum. Pseudarthrosis was formed because of pieces of muscular fibrous tissue. It was noticed during the war that surgeons were too fond of anterior incisions in the thigh. The bones took their blood supply from the femoral artery. If the lower fragment was deprived of its blood supply there would be sclerosis of the detached periosteum, with absorption, osteoporosis, and necrosis. One patient had been operated on twenty-seven times and an infected cavity had always formed. The infection in these cases was not in the bone, it was entirely superficial. It was not necessary to do a very large incision. A bad scar meant bad surgery and the formation of a sinus and ulceration. A curved incision was the best. Many patients were lost because of shock. Professor Chutro said he disagreed with Crile and agreed with Cannon. Shock was often caused by toxins absorbed from too much incision of muscle. One could do very long operations on the foot, but when one got into the hip or pelvis, and came in contact with large muscle masses, there was danger of intoxication. In an amputation passing through the muscle, patients went into shock. The subperiosteal incisions could be stood by even emaciated tuberculous patients. In operations on the tibia one could take two-thirds of the circumference of the bone, if one did not touch the anterior portion. One could remove the internal border of the tibia without touching the crest of the tibia. One had not taken too much bone. Later the periosteum would give more than enough bone. Bone was dead tissue, simply meant for purposes of support. Bone never gave bone. Bone cavities were entirely sterile. One could not fill cavities with soft tissue, because soft tissue retracted. The only substance capable of filling the cavity was muscle. In empyema one made incisions and let the lung make a hernia through the incisions. The same thing happened in muscles. The periosteum would make herniæ through the muscles. A detail in finishing the operation was the management of the flap. To prevent retraction twelve Carrel tubes were put in, with two stitches in the superior part of the flap and two in the inferior part, leaving the middle wide open. This prevented ultimate deformity. Soft gauze in contact with the flap maintained irrigation immediately after operation. The surgeon must, however, have cleaned the wound entirely, Dakin's solution could not do the surgery. Any clot formation would cover microbes and reinfect the wound. Gauze was put near the tubes to spare the patient pain and hemorrhage. Little by little the muscles would fill the defect and the the soft tissue adapt itself to the surface of the muscle. At first the technique was to close the wound when sterile, but this was a failure. In laparotomy one could not do peritonealization, and in the same way one could not close up the bone because pus would form and there would be repetition of the sinus. The bone had to be covered with granulation, but it was better to wait for cicatrization of the skin, so that the scar tissue would be far from the bone. In a large cavity of the internal condyle of the tibia, the cavity must be cleansed and a plastic operation done by taking fascia and muscle from the anterior part of the thigh. One cavity was filled with a piece of patella. The man had refused amputation and was a desperate case, but he got cured. In fracture of both bones of the lower tibia, sometimes resection of the superior wall had been done and sometimes of the posterior wall. Every type of case had its own procedure, but it was preferable to resect the posterior wall, because of the form of the anterior part of the leg in the standing position.

Method for Ensuring Immediate Closure of Wounds.—Dr. W. W. Babcock of Philadelphia presented this topic. He said that two points stood out in treatment of injuries: (1) the excellence of surgery required; (2) the superlative quality of dressings required over a long period of time. If one could find some powerful solution which would destroy the bacteria in the wounds and secure immediate closure, it would be of immense advantage. They had operated sixty-four cases with immediate closure after sterilization on the operating table. Patients were treated with a saturated solution of chloride of zinc, saturating hydrochloric acid with pure zinc. An injection of methylene blue was made and then, following the blue area, all dead material was removed. Complete closure of the wound was then done with muscle against bone. Sections made of scrapings from infected sinuses had shown no growth, demonstrating the efficiency of the method. Zinc chloride could drive into the tissues with great speed. A very long, straight incision was made, freely separating the skin, sometimes entirely around the limb. The skin and fascia were left and the periosteum with bone attached. The periosteum was lifted off the bone, so as to free the muscles and fill the cavity. A mass of diseased bone was taken out. A grooved surface was left in the tibia. It was expected that there would be a large proportion of stitch abscesses and phlegmons, but this did not occur. Hematomata with superficial suppuration had occurred. All the cases had healed. A shallow saucer shaped operation was made in the bone. This method would be of use in those cases of infection and reinfection which filled the hospitals. In some cases a section of the femur had been taken out and muscle allowed to fall in to fill the cavity. In one boy, taken from the train, a free incision in the tibia was done; he was sewed up tight and the wound was closed without any trouble by the eleventh day.

Nonunion Following Corrective Osteotomy of the Tibia.—Dr. Emil Geist of Minneapolis, Minn., made this presentation. Two cases were reported. The first, occurring in the speaker's own practice, was that of a healthy boy, two and one-half years of age, who was born with congenital unilateral deformity of the leg; that is, anterior bowing of the tibia at its lower third, combined with inward bending (crus varus). The bone was firm and inelastic; there were no rickets. Osteoclasis was performed. The bone was quite sclerotic. Plaster was applied from toes to groin with leg in good position, and the wound healed by first intention. Eight or nine weeks later the cast was removed and "delayed union" was found to exist. Another cast was applied for two months, at the end of which time "delayed union" still persisted. Following application of a third cast, there was still no union. All sorts of laboratory tests were made, glandular extracts tried, but with negative results. The leg was kept under *x*-ray observation for nine months, but showed progressive conical absorption of the bone ends. Two Albee inlay operations were tried, but the results were again nonunion. The boy still, at seven and one-half years, has a straight leg, ununited, which he uses with a brace. The second case was that of a young man who wanted to have his bowlegs straightened so he could go into the army. Operation was done on both legs, but complete nonunion supervened, and the man was left in the deplorable condition of having ununited fractures of both tibiæ. He was a healthy young man, with negative Wassermann. He had been a good athlete previously. Later a typical Albee sliding graft operation was done on the right tibia, which was successful. Four months later this was done on the left leg, but it was too early to report results. Thus there were still factors in nonunion of fractures, without interposition of foreign tissues and without recognizable constitutional disorders, which were not understood. The question might be raised whether, in some persons, there existed an idiosyncrasy of the osteoblasts toward the *x*-ray.

Diagnosis and Preoperative Treatment of Peripheral Nerve Injuries.—Dr. Murray S. Danforth of Providence, R. I., presented this communication. The studies were made in the Edinburgh War Hospital, in the service of Sir Harold Stiles. Diagnosis was based on history taking and the following points were specially noted: (1) Date of wound: (2) character of wound and amount of suppuration; (3) date of healing; (4) did paralysis occur at time of wound, or occur subsequently as result of scar compression; (5) was paralysis increasing or diminishing; (6) were areas of anesthesia increasing or diminishing. The routine physical examination was then made and included: (*a*) Location of wound or scar, indicating whether the paralysis was caused by the missile or the scar; (*b*) character of scar, whether soft, indurated, or suggestive of latent infection; (*c*) condition of joints in affected extremity, describing accurately the range of voluntary and passive movements; (*d*) examination of muscles, as to voluntary power and electrical responses, the former requiring great experience and being of great importance in regard to future function of the joint. Contraction of the muscle, however weak, meant voluntary power. Tightening of the tendon also meant voluntary power, unless due to change of position of the joint. The testing of response to electrical stimulation was given by using an ordinary combined battery, the limit of galvanic current being obtained from forty dry cells. The current could be changed from faradic to galvanic, the response to faradism being tested first. If there was no faradic response, the current was changed to galvanism. In the later the *character* of the response was the important point. It varied from the sharp contraction of normal muscle to the slow contraction of muscle with nerve supply cut off. Special charts were designed for recording voluntary power in muscle and degree of electrical response: (*e*) Examination of cutaneous sensibility, sensibility to cotton and to pin prick was noted, the patient not being allowed to look at the part tested; the area was shaved if necessary; (*f*) description of trophic disturbances were noted (changes in color and appearance of the skin, changes in nails, nutrition of muscles); (*g*) distal tingling; caution was used in interpreting this sign, but its presence gave a reasonable assurance of physiological continuity of the nerve. The examination outlined above furnished the bases for the diagnosis and determined the treatment. Single examinations were never accepted as sufficient to indicate operative measures, except possibly correction of deformities. As a rule, one examiner made all the tests. In this way possible discrepancies were noted between results of voluntary power tests and electrical responses. In case of discrepancy, the tests were reinstituted and the reason ascertained. Complete loss of voluntary power, with loss of faradic excitability, and with slow galvanic response, associated with anesthesia and analgesia, over the area supplied by the nerve and absence of distal tingling to the site of injury, meant physiological loss of continuity in the nerve trunk. Only repeated examination could indicate the probability of anatomical loss of continuity or that recovery would not take place. The condition known as "functional paralysis" was found to yield promptly to appropriate treatment. The general rule, in regard to treatment, was to wait six weeks to two months after complete wound healing before operating, and during that time to make two or three complete examinations. The preoperative treatment consisted in improving the nutrition of muscles, correcting any deformities, and restoring flexibility of the joints in the affected extremity. If no deformities were present the muscles were protected from stretching by proper splinting. This was important. Treatment was also given by hot soaks, whirlpool baths, massage, and electrical stimulation. Restoration of flexibility of joints, especially the finger joints, was the most difficult part of preoperative treatment. Elastic traction by means of various apparatus was successfully carried out. Massage and passive motion were used in association.

Operative Treatment of Paralytic Conditions of the Upper Extremity.—Dr. Arthur Steindler of Iowa City read this paper. Three types of paralysis of the upper extremity might be distinguished as regards functional grouping: (1) Shoulder type, involving deltoid, supra, and infraspinatus muscles, with inability of elevation and outward rotation of shoulder; (2) shoulder and elbow type, involving coracobrachialis, Brachialis anticus, triceps, supinators, and often also extensors of the forearm, with loss of shoulder action and flexion of elbow and pronation contractures; (3) general type, involving additionally the muscles of forearm and wrist, more often extensor groups and intrin-

sic muscles of the hand. In general it was noted that fingers and wrist more often escaped paralysis than shoulder and elbow. Group (1) represented the fifth and sixth cervical roots; group (2) the fifth, sixth, and seventh cervical roots; group (3) the fifth cervical to first dorsal. Spinal motor roots, however, were not representative of motor nuclei in the anterior horn, so that the relationship of paralyzed muscle groups must be sought in the motor cell groups. Cell columns were seen in cross section, in typical clusters, on the anteromedian portion, representing the dorsal and thoracic muscle groups, while the columns for shoulder, elbow, and hand appeared respectively in columns occupying the anterolateral, lateral, posterolateral, and central fields of the anterior horn. Pathological changes, therefore, might result in clinical paralyses of coordinated muscle groups, not conforming to either peripheral or radicular distribution. Thus many distinct operative interferences might be called for. Essential requirements for function of the upper extremity were: Active abduction, or apposition of abduction of shoulder; ability of flexion of elbow, ability or pronation of forearm hyperextension, either active or passive of wrist; active flexion of the metacarpophalangeal joints, free play of fingers, and power of opposing thumbs to fingers. Problems to be considered, therefore, were: (1) Procuring of abduction of shoulder; (2) procuring of flexion in flail elbow; (3) overcoming of flexion contraction in wrist and substitution therefor of stable hyperextension, (4) overcoming claw hand deformity and securing flexion of metacarpophalangeal joint; (5) procuring powers of opposition for thumb, and active extension. In flail shoulder there did not seem to be any reliable method of tendon transplantation. The indication here seemed to be arthrodesis; this need not be complete, however. The operation consisted of a horseshoe incision circling the acromium, isolation of deltoid muscle, the acromium was then cut through, and the deltoid with acromial insertion turned down to give access to the shoulder joint. Part of the head was resected and the glenoid fossa reamed out. The raw bone surfaces were united with wire, the capsule reefed and closed. The deltoid flap was transferred back to the spine of the scapula, forcing the head of the humerus forward, thereby giving better control of the shoulder movement by the trapezius. The shoulder was held in a platform splint at right angles for four months. The problem of flail elbow was difficult, as the arthrodesis could not be undertaken in children under fourteen or fifteen years of age. Even then it was doubtful. Operation consisted in causing the flexors and extensors of the wrist to act as flexors of the elbow, but flexion was limited and was of use only where the muscles were not weakened. Plaster cast for two months was used, then a splint with a stop lock for six months, not allowing over 90° of extension. In drop hand and flail wrist, stabilization of the wrist was an advantageous procedure. The result of the operation was not a complete arthrodesis, but rather limited wrist motion, from 10° to 30° of extension. Tendon transplantation was done in addition in several cases. The operation of flexor plasty was done with advantage in restoring opposition of the thumb and thus the function of the hand. The flexor tendon was split longitudinally and the outer half carried around to the outer side of the base of the basal phalanx of the thumb and there fastened. This operation was often performed in addition to other work on hand and forearm. Lack of extension of the thumb was corrected by the method of Mayer and Biesalski, by taking the extensor of the index finger as a check to the flexors of the thumb. For flexion of wrist in mainen-griffe flexor plasty was done in some cases, and the cock-up splint of the kind devised by Sir Robert Jones was used in other cases. Modifications of this had been devised for correction of hyperextension position of the metacarpophalangeal joints. In most of the cases reported a combination of operative procedures was carried out. Operation in one joint often benefited a neighboring joint. Flexor plasty of the elbow, combined with arthrodesis of the shoulder, gave better functional result than in cases where arthrodesis of the shoulder was not done. If arthrodesis of the wrist had been carried out in connection with elbow plasty, the elbow results would have been better.

Infectious Arthritides, with Especial Reference to Foci of Infection.—Dr. VIRGIL P. GIBNEY of New York presented this communication. In the single, multiple, hypertrophic, and atrophic types of cases one had to watch for end results. Opinions could be taken in regard to the cases from laryngologists, otologists, rhinologists, genitourinary men, and internists. The tonsils could be treated, the teeth *x*-rayed, and films sent to the dentist. Cultures could be taken of tonsillar foci, and vaccines could be made and followed up. Failing result from that, the genitourinary and intestinal tracts could be treated. In highly acid or highly alkaline stools, with immense amount of indol and skatol, implantation of *B. coli* would help. With all this, however, results were often disappointing. No foci seemed to be of prime importance. The damage had been done. One had then to resort to orthopedic measures. Arthrotomy could be tried. Earlier and milder cases would respond to systemic treatment.

Bone and Joint Lesions from Focal Infections.—Dr. S. L. MCCURDY of Pittsburgh presented this paper. Infections from the teeth, tonsils, alimentary canal, genito-urinary tract, were common. The tonsils in children gave rise to acute inflammatory cases. Metastases might take place into the lateral sinuses, followed by meningitis and death. In regard to pyorrhea alveolaris, 60 per cent. of so called arthritis cases had pyorrhea. The hypodermic use of emetine would clear up the mouth. Foot troubles might ensue because a man neglected his mouth. Rheumatic joints were secondary active pathological foci. Of 28 skeletons of men taken from the morgue, 8 had vertebral columns ossified and other ankyloses. These were the type of men who never used a tooth brush. Three cases seen were associated with intestinal stasis and constipation and visceroptosis. One girl with a stiff elbow was treated with buttermilk, putting the right kind of bacteria in the intestinal tract. This broke the adhesions up. Four cases were associated with gonorrhea, gleet, or syphilis. The majority of these cases were venereal. In plasmodial infections, emetine hydrochloride, 10 per cent. would cause disappearance of symptoms. Constitutional treatment could be given with potassium iodide, salvarsan, or arsenic in some form. The only conclusion one could come to was that the source of infection had to be cleared up. Changes in the skeleton could not otherwise be stopped.

Personal Experience with Lane's Plate in Fractures.—Dr. PAUL P. SWEET of Hartford, Conn., read this paper. Among 1560 fractures of the long bones observed during a three year period, there were 172 open operations; 41 for compound fractures, and 129 for reduction of simple fractures, and delayed, non- or vicious union. Lane plates were applied in 28 instances, as follows: femur, 18 cases; tibia and fibula, 7 cases; radius and ulna, 3 cases. Primary healing of the operative wound was obtained in every case except two, in which they were used in compound fractures with severe displacement. Excellent final results were obtained, however, in spite of this risk. In four cases sinuses developed after some weeks. The process was afebrile and resulted from foreign body irritation. On removal of the plates, the sinuses closed, excepting in one instance in which there was a low grade osteomyelitis caused by the plate. The plates and screws in this instance had been handled by the operator, but this fault in technic need not have occurred. The patients were all urged to have the plates removed after firm union had taken place, and this was done in four instances. No abnormal bony reaction or tissue reaction had been found. In one case of non-union of the femur, operated upon 1½ years after injury, a large 6-screw plate was used, and in spite of protests, the results had been excellent. Probably removal of considerable bone, and apposition of healthy non-sclerotic fragments explained this success. The cases of sinus all occurred in the radius and ulna, or tibia and fibula; there was no trouble in any of the femur cases. It would seem then that Lane plates offered a satisfactory means of fixation in selected cases. They were more efficient than other agents in highly comminuted fractures, where other fixation materials might increase the trauma.

Points to Be Observed in the First Ten Days of the Treatment of Compound Fractures.—Dr. H. WINNETT ORR of Lincoln, Neb., made this presentation. The

speaker said his paper was a plea for the immediate or very early restoration of parts in a compound fracture to as nearly a normal position as possible. Following these methods of fixation which actually do maintain position with length and in which the immobilization is as perfect as possible, experience of the war hospitals had shown that in thigh fractures the use of the Thomas splint and plaster of Paris, or both in some cases, might be made to meet practically every indication. In leg fractures the same thing was true, with a wider field of use for plaster of Paris. In fractures of the upper arm there had been a tendency for too long continued use of the long Thomas splint. The importance of elbow flexion and supination of the hand to be done not later than two weeks from the time of injury was emphasized, especially in fractures of the humerus. Plaster of Paris might also be of the greatest use in these cases. Supination in a Balkan frame in all of these fractures was frequently important and necessary, but the use of weights and pulleys in this connection should not be confused with the occasional use of weights and pulleys for traction, which should certainly be used much less than heretofore.

Disability Following Injuries to the Back in Industrial Accidents.—Dr. JAMES WARREN SEVER of Boston made this presentation. Attention was called to the fact that persons suffering injury to the back in industrial occupations suffered long periods of disability therefrom. Two facts were noted in these cases, first that the disability was unusually long, and secondly that medical supervision was not of the best, nor calculated to get the best results. One hundred and thirty-four cases were reported, comprising: those injured by falls, 61; those injured by direct blows in the back, 31; those who had injured their backs by lifting strains, 42. Class I included 59 men and 9 women. In all cases injury was by fall from a height, in one instance as much as 70 feet. There were in some cases accompanying fractures of legs or arms. There were 24 cases of fracture of the vertebrae. Leaving out these, the average period of disability was about 6 months. The spinal fractures averaged 17 months of disability. These figures did not really represent total period of real disability, but covered the time elapsed from the accident, until seen by the speaker as an impartial examiner from the Industrial Accident Board. In some cases it was believed that the man should try and go back to work, but there was no doubt a psychological factor in many cases. While one could not say that any were real malingerers, the fact that they received compensation without working had a good deal to do with disability in many cases. In considering the type of treatment accorded to the cases suffering from contusions of the back, it was found inadequate in 20 cases out of 37. There was no doubt that if proper and skillful medical attention had been given, the disability periods would have been cut in half. In regard to the fractured vertebrae, many of these were unrecognized and went around with strapping or wore belts for sacroiliac strain. Many left the hospitals without support for the back. Occasionally there was a quiescent hypertrophic arthritis in the spine, which lighted up after the accident. This hypertrophic arthritis might so alter the appearance in the vertebrae that fractures were suspected, and one had to interpret *x*-ray findings most carefully. The speaker believed that the American Orthopedic Association should discuss the question of hypertrophic arthritis of the spine in relation to industrial accidents and compensation claims. Class II represented cases injured by direct blows by falling objects. These cases suffered most from muscle contusion, apart from fractures. The accidents occurred to laborers, plumbers, teamsters, etc., and were usually the result of their occupation. In this class of 31, there were 7 spinal fractures of the spine. The treatment was inadequate in all cases. It was not the general practitioner alone at fault. Hospitals were to blame for the careless methods of examination they allowed by their house officers, and condoned by visiting physicians. The question of treatment of these fractures was highly important from an industrial point of view. Should they be treated with a net minimum period of fixation, and then gradual use, or should they have a long period of fixation with plaster jackets and back braces. Should one continue fixation as long as symptoms continued; would restricted use begun early make the back more irritable, or would it lead to earlier restoration and function? Orthopedic men should be able to answer these questions. Class III injured their backs by heavy lifting strains. Any definite classification of the cases was difficult, many receiving muscle or ligamentous tears, and very few the typical sacroiliac strain. There were 42 men in this class, with an average age of 40 years. All had heavy lifting to do as a routine. The average period of minimum disability was about 5 months. Adequate treatment had been given in about one-fourth of the cases. Strapping with sticking plaster seemed to be the usual treatment. It should be remembered that strapping was an art, and unless done mechanically correctly it would fail. Control of the patient and careful and adequate physical examination would lead to more comprehensive treatment, an essential all too often neglected. The medical profession had reached a stage when their work would be checked up by industrial legislation, and they must make good.

Application of Curative Therapy in the Ward.—Dr. HENRY CHASE MARBLE of Boston, Mass., read this paper. During the past few months the terms had crept into use: Occupational Therapy, Physio-therapy, as if each were an end unto itself. This was a serious mistake. All forms of therapy were all united to one end under a competent surgeon, who pooled his resources to achieve a successful whole. Nurses, orderlies, aides were at his disposal. The latter, working under the direction of the ward surgeon, strove, through simple and graded occupation, first for mental rehabilitation, second for restored function. Direction of a medical officer was necessary so that the correct amount and type of work might be given. Often men most in need of occupation were the hardest to start. Rarely did a man do more than necessary and have to be slowed down. When the patient was up in a wheel chair or about on crutches, some attempt could be made, under careful supervision, toward functional restoration. The required time should be given to occupational therapy, or it failed in its purpose. Physio ward work was of another type. The aide, under supervision of the medical officer, endeavored to prevent deformity, and to stimulate motion. Careful records were kept of improvement. In muscle wounds, after closure, early motion was the policy. The barometer of motion was always pain. In Base Hospital No. 6 the daily visits included the ward surgeon, the nurse, the enlisted man who acted as splint man, and two aides, occupational and physical. The type of occupational work most suitable was rug making, toy making, weaving, stenciling, printing and bead weaving. On account of short personnel there was opportunity to compare wards where there were no reconstruction aides at work. The result was overwhelmingly in favor of wards with aides. Charting methods were used to measure return to normal function, which the soldiers followed with delight and encouragement. Measurements were made upon an apparatus with a dial, so that a fair degree of accuracy was obtained.

Application of Curative Therapy in the Workshop.—Dr. E. B. MUMFORD of Indianapolis presented this branch of the subject. Great success had attended the close cooperation of the orthopedic department with the educational and physiotherapeutic departments. The officers of the educational department were members of the Sanitary Corps, and had little or no training in medicine and surgery. They took charge of gymnasia, manual training and bedside work. After a conference between the chiefs of the educational, psychiatric, and orthopedic departments, it was decided that the work of the hospital was curative, not educational. Peripheral nerve injuries were delegated to the orthopedic surgeon, and deformities with loss of function were treated by physiotherapy under his direction. Thus the orthopedic service had practical control of this work. The cases treated included all classes except amputations. Most of the men had been in hospital several months and under care of many different ward surgeons. Improvement was often a matter of guess, and most were being held merely to stabilize the lesion, so as to judge of disability. These men were turned over to the orthopedic surgeon, and he compiled a record card which gave a brief description of the disability,

the range of motion, etc., and notation was made as to treatment to be followed. A record was kept of muscle power and range of motion. The patient had a schedule of hours at which he was to report to various clinics, and if he were not found in attendance at his clinic he could not say "I forgot." He was enrolled in one or more educational classes, which were entered on his card. The patient had four different clinics in all to report to every day: Gymnasium, workshop, massage, and vocational. The day was divided into periods and the workshop period was a full two-hour period. The men could be kept there longer than the gymnasium. The gymnasium and physiotherapy occupied one hour each, and educational work a one-hour period. The keynote of all this work was direct and personal control of all branches by the orthopedic surgeon. Exercises and games were directed to correction of different types of cases, and shower baths, with a brisk rub, terminated this part of the work. In the workshop an expert teacher was engaged, but attention was concentrated on the curative side of the work. It was impressed upon the patient that a poor article made with a crippled hand would get him out of the hospital quicker than a good article made with a well hand. Close attention was necessary to see that the patient did not shift the tools to the well hand, as he was apt to do in his interest in the work. Massage and allied clinics were under control of the orthopedic surgeon, and the men received massage on returning from the workshop. Each week results were tabulated on the patient's record card. If no gain was recorded, examination was made to see if the patient was attending clinics regularly and, if so, whether treatment was suited to his needs. If the maximal improvement had been reached, papers were prepared by the orthopedic surgeon in charge, recommending the case for discharge by the Disability Board. The data of hospital progress and degree of motion in the affected joint, as compared with the corresponding joint, served as a basis upon which to adjudge disability. At first morale was poor, as the patients had been hospitalized a long time and many would rather have gone out with their present disability, but after a short time the men realized that the staff were working for improvement in function and also for their discharge from the army. They became interested in their progress and a personal pride in the gains made. The fact that they could not be discharged until the orthopedic department was satisfied that maximal improvement was reached was an important factor in regular attendance. In some cases the patients seem to go back and lose range of motion, but after a week's rest they made better progress than previously. These cases were probably due to muscle spasm from overexercise. The wrist cases were most apt to show less. In conclusion, the work had been of value not only in a curative way, but had also hastened the discharge of the patient and lessened his hospitalization, saving money for the Government and returning the soldier to civil life at an earlier date. The work in the gymnasium improved the general physical condition and awakened an interest in gymnastics which it was hoped the patient would carry to his home town. In all branches the patient was taught things to make him a better and more useful citizen. Psychiatrists would no doubt agree that a day full of interesting work saved many men from a life of insanity caused by the electric piano in the recreation centers.

The Industrial Rehabilitation of the Cripple.—Dr. CHARLES H. JAEGER of New York City presented this topic. At the International Conference it was stated that the Educational Board expected to train over twenty thousand crippled soldiers. It could be stated also that there were about one million industrial cripples in the United States. What a handful the war cripples seemed beside the numbers of industrial cripples! The idea was started in 1912 that a great economic waste was originated by the support of cripples in industries. Before the war society felt that it could afford this expense, but the war had taught the inhumanity of this attitude. In former times the crippled man always wanted to be a watchman. In 1912 it occurred to the speaker that it would be a good idea to train these cripples in some well-paid occupation, such as silversmithing. A class was started and there were a large number of successful graduates. One boy who had been a cowboy and had lost both legs in an accident was sent to the Almshouse on Blackwell's Island, where surrounded by human derelicts he was rapidly going down hill, when he was brought into the class. He improved very much and got a good position as a silversmith. He fell back one time and went back to begging, but the final report of him was that he had picked up again and gone back to work at his trade, where he meant to stay out. Engraving was another very well paid trade. The teachers in this branch were men actually out of the trade and who knew the requirements of the trade. Reed furniture offered a promising livelihood for a man to open up business for himself as it required no great outlay in tools or materials. One postman with an injured knee, discharged from the postoffice, and who got into an extreme state of psychic depression over his misfortunes, learned this trade quickly and made a good living. Cabinet work was very well worth while. One crippled boy of seventeen, mentally deficient, learned this work in six months and got a big job in a piano factory. His mental powers increased 100 per cent., and when seen later, he was well-dressed, and had an independent, self-satisfied air. Mechanical drafting was a very good trade even for one-handed patients, and if they could also take a correspondence course in mathematics they could do very well. The disability of half a hand did not amount to anything in many trades. The mosaic glass trade was highly remunerative work. One Italian cripple who had spent several terms on the Island for begging made wonderful progress at this work. He was allowed to try and make a design for himself, and work out a beautiful grape pattern. He became exceedingly talented at this work. Shoe cobbling was another good line of business. One pupil in this class lived three miles from the school—he was at the Montefiore Home for Cripples. He managed to attend school every day and learned cobbling. He got shoe machinery and started a prosperous business. It was best to allow the men to pick out whatever they liked to do. Regular hours were kept as if the men were in their own shops. It did not do to mollycoddle them. A house in the Bronx was used for the school, but it had to be given up on account of the lack of interest of the public, and the cripples were not educated to the idea. They knew that they could make $5 a day by begging and they did not see why they should work. Another difficulty was that the hospitals did not cooperate; although every facility was offered them they did not accept what was offered. Two things stood in the way of the cripple: (1) the antagonistic attitude of the trades unions, (2) the issuance of licenses to beg, under the guise of selling pencils. The matter of discipline in the training of cripples was important because such individuals often had a warped and distorted mind. The solution of the whole matter lay in teaching the cripple to do some one thing superlatively well, so that he would be employed in spite of his disability. Industries should be made to take care of their cripples and put them in training schools.

AMERICAN THERAPEUTIC SOCIETY.

Twentieth Annual Meeting, Held in Atlantic City, June 6 and 7, 1919.

(*Continued from page* 521.)

Organotherapy in Certain Diseases and Conditions of Childhood.—Dr. E. BOSWORTH MCCREADY of Pittsburgh, Pa., read this paper. (See page 529.)

The Present Aspects of Endocrinology.—Dr. A. W. LESCOHIER of Detroit, Michigan, presented this subject. (See page 532.)

The Medical Treatment of Goiter.—Dr. GRANVILLE M. RYAN of Des Moines, Iowa, presented this paper. (See page 534.)

The Curative versus the Symptomatic Treatment of Goitrous Disorders.—Dr. C. E. DE M. SAJOUS of Philadelphia presented this paper. (See page 536.)

Dr. O. T. OSBORNE of New Haven, Conn., said that in the first place, no matter how many data the laboratory had furnished, nor how much was read on the subject, the results from therapy had to be reached through clinical study. One knew from clinical study that ad-

renalin raised blood pressure, yet the laboratory men were saying that it had nothing to do with blood pressure. The first thing was to study the patient, physically, mentally, and psychologically to find out what was wrong and how to correct it. It might be necessary to give some drug, or a dose of a gland to test the case and find out whether the gland was hyper- or hypoactive or simply absorbed. Here it would be well to state that the rapid heart (130) without dyspnea was always thyroid. One saw a patient with a pulse rate of 200 and one asked "How many pillows do you need at night?" If the patient said "only one," that was a thyroid case. In regard to focal infection, in examining men for the army, the N. C. A. cases, one looked at the mouth and found that in about 80 per cent. of the cases there was infection, often from the teeth. In regard to Graves' disease, this was an attempt of the thyroid to counteract the effect of intoxication. Certain cases seen of Graves' disease became better on feeding thymus. One should spend more time on the question of parathyroidism—sleeplessness, nervousness, etc.; there was no question as to the necessity of rest, proper diet, and the avoidance of irritating drugs. One could also add calcium and alkalies to the treatment. This question was not so much one of myxedema or of exophthalmos, it was one of disturbance of secretion. If one could find the source of the trouble, patients would improve rapidly.

Dr. F. M. Pottenger of Monrovia, Calif., said that in regard to the question of the application of physiology to medicine, if one attempted to study the patient physiologically, one would get a different attitude to that of experimental study. He was glad to hear that Dr. Osborne pinned his faith on clinical observations rather than on laboratory work. There was a long way between a guinea-pig and a man. Clinical study of the human being was worth more than observations on the animal. Animal experimentation was carried to ridiculous conclusions. One noted physiologist made observations on the human subject in glycemia, then he tried the same thing on a dog and it did not work, and so came to the conclusion that the diagnosis was wrong! Clinical study required the same care and close attention as laboratory work, and close observation would bring out many points. It was self-evident that if disturbance appeared in the body there must be disturbance in the chemical and nervous control. The action of adrenalin belonged to the sympathetic nervous system and exercised control on the blood vessels. Small doses would cause splanchnic contraction. The study of the thyroid gland was most interesting, and he was glad to hear Dr. Sajous treat the matter in detail. The minutiæ were of great importance. One knew that stimulation of the sympathetic nerves would stimuate thyroid action, so that toxic stimulation of the sympathetic produced this result. Toxemia meant continuous over-stimulation, resulting in breaking down of body tissues and breaking up of molecules into toxic molecules. One interesting point of Dr. Plummer's work was that thyroxin worked as a catalytic agent, controlling the energy output of the body. These patients had an increased energy output of 100 to 150. This showed the necessity for physical and mental rest in order to put a check on the breaking down as much as possible. The thyroid activity was burning up the patient and increasing the amount of poison from breaking down of tissue.

Dr. Jacob Diner of New York said that it was very interesting to consider in the papers read today, that the key note was that which should underlie all medical work, namely "Seek the Cause." This was overlooked by many practitioners. If one got the cause, the symptoms would take care of themselves. Dr. Diner said he was disappointed that nothing had been said about dosage, which, in the question of internal secretion extracts, was an important thing. Manufacturing concerns had been bringing out thyroid extracts, gonads, etc., but there was no standardized and certain rule of dosage. Students were taught dosage of digitalis as so much, but there was no statement as to what dose of the drug was enough to bring out its physiological effect, whether 0.001 or 10. The dosage of gland extract was one that would produce physiological effect. The laboratory man had his place in this study and one could believe him up to a certain extent, but his work was only one link in the chain of evidence. The evidence presented by the patients was of far greater importance.

Dr. D. H. Murray of Syracuse said that he was interested in Dr. Sajous' paper and he would judge from what was said that this was one of the penalties of wrong living, which could be prevented if one started early in life by living physiologically. Most of the patients seen gave a history of drinking from 2 to 4 glasses of water a day and a cup of tea or coffee. One could not run a machine without furnishing it material to make it run. The average person passed three pints of urine every day; he breathed 20 times a minute, 1,200 times an hour and 28,000 times a day, and there was an appreciable amount of water in the breath; the skin put forth 12 to 16 oz. of moisture by perspiration every day. Thus if this fluid was not replaced one must have definite elimination from every part of the body and from the thyroid. Constipation included deficiency of elimination of the whole body, through skin, breath, urine, and bowels. To regulate the thyroid tissues one must go back to food and water and habits of elimination. It would be wise to put the patient on extra drinking water to see how much he would be benefited by such measures. Dr. Murray said he always put his patient on the left side for an enema.

Dr. H. C. Gordinier of Troy, N. Y., said that one was in a position to diagnose hyperthyroidism very early, just as was the case with tuberculosis. Early cases got well with nothing but rest, plenty of open air, and a lactovegetarian diet. Goetch of Baltimore made use of the adrenalin test which was a valuable addition to diagnostic methods in hospitals where the calorimetry method could becarried out. To illustrate what Dr. Sajous had said in regard to foci of infections, he had a case of a girl about to be operated upon, where there was an indefinite history of tonsillar infection. He had had the tonsils taken out and instituted rest treatment and the girl got well. Dr. Plummer's observations of changes in the sympathetic ganglia observed at autopsy in cases of exophthalmic goiter, were very interesting and valuable.

Dr. H. C. Wood of Philadelphia said that there were three sisters in the therapeutic art, etiology, pathology and symptomatology; the first two of these had been invited to the ball, but the third, poor Cinderella, stayed at home. To neglect symptomatology, however, was a great mistake, even in Graves' disease. Dr. Sajous had pictured very faithfully the disasters throughout the body, as the result of over activity of the thyroid gland. But suppose an automobile in the garage should set the garage on fire, it was not enough to pull the cause out of the garage and let the structure burn down. Symptomatic treatment had its place, for instance in the control of the tachycardia. There were a number of efficient remedies for reducing the heart rate. Veratrum viride was as accurate as digitalis in slowing the pulse rate, and could be used while one was waiting for etiological treatment to cause subsidence of the thyroid symptoms. He would like to ask Dr. Sajous for information concerning the effect of thyroid gland upon metabolism; it was well-known that the thyroid greatly enhanced fatty and nitrogen metabolism, yet one knew from experience with human beings that on thyroid feeding the patients began to gain weight again, despite disturbance from the full dose of thyroid. What was the reason of the apparent reversal of thyroid action?

Dr. John C. Hemmeter of Baltimore said that he had a recent letter from Professor Hamburger, president of the last International Congress on Physiology, in which the writer said that in a study of the increase of hyperthyroidism in the army in Holland, it was found to be 10 per cent. Among the German people it was 8.5 per cent. It would soon be seen in this country in the nature of an epidemic and preparation would have to be made to meet it. Ten per cent. of an army of one million would mean 100,000 cases. Were all these people then infected? It would seem more like a physiological process. Chromatolysis was a normal physiological process. Take a crow in the morning and there was no chromatolysis, but take the same bird in the evening after working in the field all day and the process was

marked. The chromatolytic process did not necessarily mean intoxication. Why should there not be a thyroid neurosis, pure and simple? He regretted to see the apparent antagonism between the physician and the physiologist. The physiologist could produce exact conditions, but the clinician could not.

Dr. RUSSELL of Philadelphia said that he could report the cases of two patients with tachycardia without exophthalmos, who were cured by ligation of the thyroid arteries. In the early stages the disease could be cured by complete rest without any use of drugs. In the cases seen on the medical advisory board, rest and proper diet seemed to be of more importance than drugs. The new treatment by the *x*-ray dosage had been tried in three cases of classical Graves' disease. It was necessary to keep the patient in bed one month, and after that he could follow his usual vocation. One patient, a nurse, was able to keep at work, while taking the intensive *x*-ray treatment. Two cases out of five were uninfluenced. Three were improved.

Dr. W. F. MILROY of Omaha said that he had noted a striking example of effect of fright on the thyroid. During the hot season when the streams were dried up a party of young people were daring each other to cross a gulley over a plank which was about ten feet from the ground and had no supporting railing. One young woman made the attempt and got across for about 200 feet, when she got dizzy and fell. She was considerably shaken up and when she came back collapsed entirely. She was assisted home. She immediately became ill and showed at once a greatly enlarged thyroid, marked exophthalmos, and a very rapid pulse. She had never had any symptoms before and was apparently in perfect health when she tried to cross the bridge.

Dr. THOMAS F. REILLY of New York said that there seemed to be one fault in these observations. This Association had members scattered all over the country, who saw all types and classes of patients. Many observations, however, went to waste and were unrecorded. It would be well to formulate a questionnaire to send out, so that some definite conclusions might be arrived at. Endocrinology, like arthritis deformans, seemed to be a sort of grab bag for the ordinary practitioner. There ought to be some concrete form of diagnosis and treatment. Many of these cases were never diagnosed. Some formula for investigation would result in much benefit for men not fortunate enough to be present at this discussion.

Dr. GRANVILLE M. RYAN of Des Moines said he would like to emphasize the fact that there was considerable neglect on the part of surgeons who operated on these cases, in not referring the patients back to the medical unit for further care. He felt that the surgical work was but one step in treatment, that the case was still a medical one and should be observed as such. Twenty years' experience of cases operated upon at the best clinics showed that the patients left without any instructions at all as to future care and conduct. Internists should follow these cases up and watch them as carefully, or more carefully, than before operation. The *x*-ray had given very satisfactory results in many cases, but it was essential that it be administered by a roentgenologist who understood handling such cases.

Dr. SAJOUS, in closing, said that he enjoyed hearing this discussion, which had been an expression of experience. In answer to Dr. Wood, he had in no way meant to lower the value of symptomatology in connection with recognition of the disease. His paper was entirely concrete, and he felt that once the diagnosis was established the symptoms were of less importance. Early cases were often unrecognized and the adrenalin test of Dr. Goetsch was going to be of great help. The point to preach in regard to symptomatic measures was that one should be careful that they did not conflict with the actual needs of the patient. In regard to veratrum viride, suggested by Dr. Wood, the speaker said he would hesitate to give this drug as it tended to lower the blood pressure in the splanchnic system, already lowered in these cases. In regard to increase of weight, after giving thyroid and then ceasing to give it, there would be increase of weight. Cases coming to autopsy often showed edematous tissues. Hyperthyroidism was often met with in stout people. In regard to hyperthyroidism in the army, one was bound to meet with an enormous number of cases in men who had been subjected to hard labor and fright. Fright was the main cause. In regard to the use of the *x*-ray, one should be very cautious in applying this agent. Surgeons found that in cases where it was necessary to apply the knife the *x*-rays had formed adhesions round the gland which rendered operation very difficult. The application of one dose a month might be of use.

(To be continued.)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, April 2, 1919.

THE PRESIDENT, COL. WILLIAM J. TAYLOR, IN THE CHAIR.

Advancement in the Treatment of Wounds and Infections Resulting from the War.—Dr. JOHN H. GIBBON, late Colonel M. C. and Consultant in Surgery A. E. F., said that as a result of the war the treatment of wounds and infections had been enormously advanced and that this must of necessity influence the practice of civil surgery. Regarding the question of new antiseptics, there was not, nor would there ever be an antiseptic that could supplant the aseptic treatment of wounds. The war had definitely taught the one great lesson in the prevention of wound infection of the immediate and complete mechanical cleansing, what the French call débridement, what we might call mechanical antisepsis. To express in a single term just what this meant the word "excision" had been employed, and Crile had made use of the term "revision," but in the author's opinion neither excision, and certainly not revision, was a comprehensive term. Such mechanical cleansing, he asserted, was the most important step in wound treatment, and the care with which it was carried out determined the proportion of wounds which might be immediately and completely closed, and the proportion of infections and deaths from infections. There must of necessity be a large majority of wounds which could not be immediately closed. The lapse of time for the occurrence of infection, the presence of comminuted bone, and the necessity for immediate transportation were factors rendering immediate suture unsafe. One of the difficult things to give up in the war had been partial closure of wounds with the introduction of drainage. Partial closure, however, he regarded as an error because it was much easier to sterilize and close a wound secondarily which had been left wide open, than one which had been partially closed with a drain. Primarily, the credit of successful wound sterilization was due to Carrel and Dakin, but certainly the surgeons in the American Service owed much to Depage, LeMaistre, Duval, and others who had elaborated or simplified the technique. Dr. Gibbons felt that he had never appreciated what the Carrel-Dakin treatment was capable of accomplishing until he had seen it properly employed in Carrel's own hospital at Compiègne. He was not prepared to say that other agents, such as dichloramine-T would not sterilize infected wounds, but he did think there was no method so universally applicable and reliable as the Carrel-Dakin treatment. This statement was made not alone upon his own experience, but upon a fairly wide observation in many American, French, and British hospitals. The two criteria for judging the germicidal power of any of the agents mentioned were said to be the fall in the bacterial count, and the ability to close the wound completely. In no field of war surgery had the advance been so remarkable as in the treatment of gunshot wounds of joints. At the end of the war a surgeon who did not close a gunshot wound of the knee joint was open to the criticism of not doing up-to-date surgery. In the treatment of gunshot wounds and infections of the chest the advance had been second only to that of joint surgery. Probably the greatest improvement in the treatment of pleural infections was due largely to Depage in his sterilization of the pleural cavity with Dakin's solution. The gas bacillus was stated to be the cause of more amputations and deaths than any other organism. The tetanus bacillus had been practically wiped out after the use of the prophylatic injections were regularly enforced.

Some Medical Impressions of the War.—Dr. GEORGE WILLIAM NORRIS, late Colonel M. C., U. S. Army, said that trench fever, the new, specific, definitely established disease of unknown etiology was the greatest incapacitating factor in the British Army. Its transmission by the body louse was universally accepted. It was virtually unknown in the A. E. F., except in the experimental volunteers. A ward full of trench fever patients was one of the gloomiest spots on earth compared with the cheer of the surgical pavilion. Experimental investigations had shown that the disease was a specific entity, due to a filtrable virus, present especially in the plasma of the blood. The infective agent might also be found in the urine and sputum of trench fever patients. Major J. E. Sweet had had seemingly almost brilliant results from the intravenous administration of collargol, although the number of cases treated was small owing to the scarcity of the drug. The term, trench foot, had been applied to the vasomotor, nervous, and trophic disturbances of the feet of soldiers exposed to wet trenches. It had been possible to relieve pain and hasten cure by the administration of sodium iodide (20 grs. t.i.d.). Influenza in the war apparently differed not at all from that seen in the United States. It was especially fatal among those who did not promptly report at sick call. At ports of debarkation the most harrowing scenes were witnessed. One transport had brought in 500 cases of pneumonia and it had been reported that the *Olympic* alone on one occasion had landed 1,500 cases of influenza; also that the *Leviathan* had bronght 1,200 cases and had had over 100 corpses on board. Ships upon which the procedure of masking was rigidly carried out had had practically no influenza. Only about two of ten chest wound cases reaching the evacuation hospital required surgical intervention, for unless there was infection, aspiration of the intrapleural blood was generally sufficient. The physical signs in such cases differed greatly from those in civil life. Nearly always the diaphgram was high on the affected side. This produced a tympanitic note at a level above that at which such a sound was normally encountered. Tympany over an injured lung was very common, and might result from free intrapleural air, relaxed lung, high abdominal viscera, gas bacillus infection. Hemothorax, pulmonary collapse, or both might occur without penetration of the chest wall; also they might occur on the side opposite to that of the injury. One of the commonest mistakes made by one not familiar with war wounds was said to be that of diagnosticating a pneumonia on the unwounded side. Cardiac displacement was regarded as one of the most important criteria for judging the location and size of an effusion. A field hospital full of freshly and badly gassed men was the most horrible and ghastly sight of the war. To see a hundred or more men, hale and hearty a few hours before, slowly strangling to death from pulmonary edema was a never-to-be-forgotten sight. The cyanotic cases were promptly bled one pint, sometimes two, and the ward, the author said, looked like a shambles. Oxygen was adminstered. Opium the physicians dared not use, for it checked an oft life-saving cough. Digitalis intravenously with timely bleeding had snatched many a man from the jaws of death. For the victims of the mustard gas but little could be done. Their faces were red and blistered, their eyes swollen shut, edematous, and weeping pus. With the removal of their clothes there came large areas of skin. Fever was present, with dyspnea, chest pain, delirium, and incessant cough. These patients died a lingering death from bronchopneumonia, and in their terminal delirum would fight their battles, curse the Hun, or call to loved ones at home. In the author's opinion no one could go through the last twenty months of the war abroad without being profoundly influenced and broadened, but that the internist profited by the acquisition of professional experience and knowledge was, to say the least, doubtful.

Physiological Experiments on Poison Gas.—Dr. ALFRED N. RICHARDS said that the purpose of his communication was to illustrate the work of physiologists in connection with the problems arising out of gas warfare. In the choice of substances having possibilities as lethal or disabling agents accurate knowledge concerning toxicity was required. For obtaining such knowledge two kinds of experimentation were required—chamber testing and field testing. In chamber experiments animals were exposed to accurately determined concentrations of gas for definite lengths of time. From data so obtained toxicity curves were constructed from which could be computed the concentration of gas required to produce death or casualty for exposures of various durations. The illustrations were drawn from work inaugurated and carried out at the British Experimental Grounds in England of which Dr. Joseph Barcroft was physiological director. In the experiments of field testing, animals were exposed to gas as liberated from shells or bombs shot from guns or detonated at rest. In such tests results were obtained which gave information concerning the properties of various gases under field conditions, the most advantageous modes of projection and the proper conditions for utilizing their offensive qualities. A brief account was given of experiments on the value of venesection following exposure to lethal gases of the chlorine-phosgene type. The results demonstrated that the mortality of gassed animals subjected to bleeding soon after gassing was regularly lessened as compared with untreated controls. An account was given of the physiological changes in the circulation following gassing, based upon the experiments of the various investigators. An account was also given of the question of protection against "mustard gas" as studied at the Experimental Field of the Chemical Warfare Service of the A. E. F. at Chaumont. The armistice prevented the final testing of the degree of protection offered by these studies.

Dr. JOSEPH SAILER stated that the opportunities in clinical medicine offered by the Army Base Hospitals at home and abroad were exceptional in the matter of the very large number of cases of individual disease presented for observation. Because of this it had been possible to test various methods of diagnosis and of treatment. At Vichy hotels had been used for hospitals, and while they were well equipped they were not ideal for the treating of cases. The fearful labor of climbing the stairs was a great disadvantage. Some of the men most worthy of praise in the A. E. F. were the stretcher bearers in the hospital centers. Perhaps 500 bed cases of a consignment of 1,200 patients would be carried from the first to the sixth floor only to be carried down again to the *x*-ray room. Not in all Vichy was there in the hotels an elevator large enough to carry a stretcher. Great difficulty was encountered in attempting to isolate the various cases—the pneumonia from the influenza, and particularly from the gas cases. Another difficulty was in handling the infectious cases. During an epidemic of diphtheria, by masking everybody in the hotel and taking cultures of everyone at intervals of 12 hours it was possible to minimize the number of cases.

Dr. JAMES E. TALLEY observed that in fifteen months serving with the Navy in France he personally had seen but one case of typhoid fever. That had been in a man of fifty-five in their own hospital who did not take the prophylactic treatment since it was not required of men of this age. Unfortunately, he had typhoid and died of perforation. In the early part of their experience they had been obliged to treat infectious diseases in one shack separated only by curtains. There were measles, diphtheria, scarlet fever, mumps and cerebrospinal meningitis, but there had been no case of crossed infection, which the speaker thought reflected well upon the nurses and hospital apprentices.

Dr. CLIFFORD B. FARR said that not all the mustard gas cases were so severe as those described by Dr. Norris. After seeing with him a group such as he had mentioned he had seen some 200 cases slightly gassed with mustard gas in which hardly a death had occurred. At the experimental field histological studies of tissure from exposed animals had been made, also pathological studies of human material sent to them from the gas hospitals. Practically all the cases of mustard gas poisoning (human) had shown destructive changes in the larynx, trachea, and bronchi; even down to the smallest bronchi the epithelium was entirely destroyed. Infection followed, so that in practically all the cases the lesions of bronchopneumonia were present. An interesting feature of the pathology was that some of the later cases showed regenerated

epithelium coming from the mucous glands and spreading out on the surface of the bronchial tubes. This was stratified squamous and not the normal ciliated epithelium. What the histological lesions might be in the cases which recovered could only be determined by autopsies in "cured" gas cases dying from other causes.

Dr. ALFRED STENGEL said that the newer ideas upon the diagnosis and treatment of empyema, and the use of immune serum in the treatment of disease impressed him as important medical contributions of the war. In the use of immune serum he had had opportunity to confirm some of the work done in the Army Service. In some work of his own about five years ago he had treated some cases of pneumococcus pneumonia with the injection of immune serum from patients just convalescing from the disease. These results were satisfactory although the work was not carried very far. In the recent epidemic of influenzal pneumonia the most encouraging results had been reported in the Army and Navy with the use of immune serum and along this line his own recent experience had been confirmative. Of fifteen cases of pneumonia so treated two had died. He expressed the opinion that if the use of immune serum could be put on a basis of usefulness for pneumococcus pneumonia, as well as for influenzal pneumonia, there would have been acquired something of extraordinary value.

Dr. JOHN H. W. RHEIN could not say that very much that was new had come out of the study of the nervous phenomena of warfare. Probably the greatest problem was presented by the condition termed "shell shock." Profiting by the experience of the English, the Americans established neurological hospitals some distance behind the lines and made provision to send patients from the field hospitals to the Army neurological hospitals from which they were evacuated to Hospital No. 117 provided for neurological cases. It was estimated that 80 per cent. by these provisions could be restored and not sent back to the hospitals.

Dr. H. A. MACKNIGHT observed that in the surgical cases which had been gassed the administration of ether caused such patients to become cyanotic, but that with ethyl chloride an operation of half an hour or an hour could be carried out without alarming symptoms. The French, he said, used ethyl chloride quite extensively.

Dr. S. SOLIS COHEN asked Dr. Stengel if he did not recall the observations made by Dr. William E. Hughes something like thirty years ago at the Philadelphia Hospital with Dr. Carter now of Texas, who was then an interne, on the use of convalescents' sera in pneumonia. Hughes and Carter had treated quite a number of cases with striking results, following the method of two German physicians named Klemperer. They then gave up the method because of a number of failures. Dr. Cohen stated that the serum of convalescents from scarlatina had been used for many years both in Europe and America with excellent results, and that many suggestions had been made, or attempts instituted, for similar procedures in all infections, including even gonorrhea, syphilis, and tuberculosis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago and New York, December 2-19, 1918.

(*Concluded from page* 486.)

BACTERIOLOGY, IMMUNITY AND MEDICAL ZOOLOGY

1. (*a*) What are the morphologic and cultural characteristics of the influenza bacillus? (*b*) Name other pathogenic organisms having cultural characteristics similar to the influenza bacillus.

2. (*a*) What are the morphologic and cultural characteristics of the anthrax bacillus? (*b*) Given a lesion suspected of being malignant pustule; detail methods for laboratory diagnosis.

3. (*a*) What are some of the characteristics which distinguish the group of nonpathogenic acidfast bacilli from *Bacillus tuberculosis?* (*b*) What is Koch's "old tuberculin," and in which diagnostic procedures is it employed? (*c*) Discuss the technic and interpretation of the von Pirquet tuberculin test.

4. (*a*) Briefly outline the theory of complement fixation. (*b*) What are the chief points of difference between the Noguchi and original Wassermann tests for syphilis? (*c*) In view of the confusion in the use of the terms "vaccine" and "serum" by laymen, state the correct application of such terms.

5. (*a*) Briefly give the life history of the parasite causing trichinosis. (*b*) What are the laboratory methods for diagnosing this infection?

PHYSIOLOGY.

1. (*a*) Describe the conditions regulating the gas exchanges in the lungs. (*b*) Discuss the theory of oxygen secretion, and state under what conditions it is supposed to take place.

2. What are the relations to metabolism of "vitamins" and "protective substances" in the diet, and in what foods are they found?

3. Discuss the respective functions of the glomeruli and convoluted tubules of the kidney.

4. Discuss the functions of the pituitary body.

5. How will high relative humidity of the air affect the loss of heat from the skin at 85 F. and 35 F., respectively?

6. What relation exists between the force of the heart beat and cardiac nutrition, and why?

7. Discuss the relations of the semicircular canals of the ear to the equilibrium of the body.

8. What are the mutual relations of the internal secretions of the pancreas, thyroid, and the chromaffin tissues as regards the mobilization of sugar in the organism?

MEDICAL JURISPRUDENCE.

1. Name three causes of sudden death, and describe the conditions found in the organs chiefly involved in each.

2. Describe the evidences of a burn: (*a*) From each of three external causes point out the characteristics which would determine the material which caused the burn. (*b*) What are the characteristics of the scar caused by a burn of the first degree? second degree? third degree?

3. What is insanity as construed by law? (*a*) Give a brief description of paranoia. (*b*) Name some of the criteria of insanity. (*c*) Describe postalcoholic psychosis.

4. A person was found dead, to all appearances strangulated, in a room where illuminating gas was so free in the room that it was easily detected by smell. How would you definitely determine whether the individual died of strangulation or by inhalation of gas?

5. Give the usual motives which cause individuals to feign or simulate disease or injuries. (*a*) How would you detect feigned deafness? (*b*) How would you detect feigned ankylosis of the knee? (*c*) How would you distinguish a self-inflicted carbolic acid burn from any other burn?

ANSWERS.

BACTERIOLOGY, IMMUNITY, AND MEDICAL ZOOLOGY.

1. The *influenza bacillus* is a small bacillus, about 0.5 micron long by 0.2 micron wide; it has rounded ends, does not form spores, is non-motile. It grows on media containing blood or pus. "Influenza bacilli do not grow at room temperature. Upon suitable media at 37.5° C. colonies appear at the end of eighteen to twenty-four hours, as minute, colorless, transparent droplets, not unlike spots of moisture. These never become confluent. The limits of growth are reached in two or three days. To keep cultures alive, tubes should be stored at room temperature and transplantations done at intervals not longer than four or five days."—(Hiss and Zinsser.)

The Pseudo-influenza bacillus, and the Koch-Weeks bacillus of conjunctivitis have cultural characteristics similar to the influenza bacillus; except that the Koch-Weeks bacillus can grow on media without hemoglobin.

2. BACILLUS ANTHRACIS. *Morphology:* It is a large, rod-shaped microorganism, with slightly thickened ends; it is from 5 to 10 microns in length, and a little more than one micron in breadth; it has a tendency to

form long threads; it is nonmotile and nonflagellated; it is aërobic. *Cultural characters:*—It grows on practically all media, as a film on potato, in tree form in gelatin stab, it liquefies gelatin and also serum.

"In taking material from a malignant pustule before excision, be careful not to manipulate it roughly, as bacteria may enter the circulation. Make cover-glass preparations, staining by Gram. Make culture on agar. Blood cultures are usually only positive later in the disease. Inoculate a guinea-pig or a mouse subcutaneously. The guinea-pig dies in about forty-eight hours and shows an edematous, gelatinous exudate at site of inoculation. The blood is black and swarms with anthrax bacilli."—(Stitt's *Practical Bacteriology.*)

3. *Characteristics which distinguish non-pathogenic acid-fast bacilli from Bacillus tuberculosis:* (1) They grow readily on any media; (2) they show more or less abundant growth or colonies in twenty-four hours; (3) they have no pathogenic power for guinea-pigs when inoculated subcutaneously; (4) they do not require body temperature for development, but grow at room temperature. (Stitt).

Koch's old tuberculin is a concentrated 5 per cent. glycerine bouillon culture of tubercle bacilli. It is employed in von Pirquet's test in the intracutaneous inoculation, and in the ophthalmo-tuberculin reaction.

Von Pirquet's tuberculin test: "After sterilization of the patient's forearm, two drops of a 25 per cent. solution of 'old tuberculin' (tuberculin 1, salt solution, 2, and 5 per cent. carbolic acid in glycerine, 1) are placed upon the skin about 6 cm. apart. Within each of these drops scarification is done, and the skin between them is sacrificed as a control. Within twenty-four to forty-eight hours, in tuberculous patients, erythema, small papules, and herpetiform vesicles will appear, The reaction is irregular and more reliable in children than in adults. According to recent investigations, about 70 per cent. of adults show a positive reaction, and in such cases it is probable that an old healed tuberculosis may give rise to a positive test where absolutely no active process exists."—(Hiss and Zinsser's *Bacteriology.*)

4. *Complement fixation:* "The reaction depends upon the fact that when an antigen, *i.e.*, a substance capable of stimulating the formation of antibodies in animals or man, is mixed with its inactivated antiserum, in the presence of complement, the complement is firmly fixed by the combined immune body and antigen in such a way that it can no longer be found free in the mixture. If such a mixture is allowed to stand at a suitable temperature for an hour or more, and to it is then added an emulsion of red blood cells, together with a suitable quantity of inactivated hemolytic serum, no hemolysis will take place, since there is no free complement available to complete the hemolytic system. If, on the other hand, the original mixture contains no antibody for the antigen used, the complement present is not fixed and is available for the activation of the hemolytic serum later added. The reaction thus depends, in principle, intimately upon the fact that neither antigen alone, nor amboceptor (antibody) alone, can fix complement, but that this fixation is carried out only by the combination of antigen plus amboceptor. Any specific amboceptor can be determined by this method, provided the homologous or stimulating antigen is used; and *vice versa*, by the use of a known antibody a suspected antigen may be determined."—(Hiss and Zinsser's *Bacteriology*).

The Noguchi method of the serum diagnosis of syphilis is a modification of the Wassermann reaction. This latter Noguchi modifies as follows: "(1) He prepares the antigen by extracting a lipoid substance from the liver and heart of dogs and cows. (2) Instead of using sheep's corpuscles in the hemolytic series, he employs human corpuscles, owing to the fact that a certain percentage of human sera tested produced hemolysis of the sheep's corpuscles. (3) In his test, therefore, he obtains the hemolytic amboceptor by immunizing rabbits with washed normal human corpuscles. (4) Another important improvement in the technique is the preservation of the specific antigen and the hemolytic amboceptor, which rapidly lose their strength in solution, in a dried form by soaking measured strips of filter-paper (.5 mm. square) with each."—(From Tyson's *Practice of Medicine*.)

"A *serum* is a product obtained by injecting into an animal, usually the horse, a culture (*e.g.* Diphtheria) or the toxin from a culture (*e.g.* Streptococcus) of the organism.

"A *vaccine* is a finely divided suspension of killed cultures of a microorganism which is injected directly into the human subject. The object is to stimulate the individual to elaborate his own antibodies, which results in increased resistance to the ravages of bacterial infection.

"Briefly, the difference is that with a serum the opposing influence to the toxins is produced outside the human body, while with the vaccine it is produced inside and the degree of immunity conferred is greater with the latter than the former."

5. *Trichinosis* is caused by the *Trichinella* (or *Trichina*) *spiralis*. "Man obtains his infection from eating raw pork, the embryos encysted in the muscle of the hog being liberated in the stomach, and the males and females developing in the intestine where, after fertilization of the females the males die, and the females bore into the intestinal mucosa and begin to produce embryos to the number of more than 1000 each. These gain access to the lymph channels and are distributed by the blood stream to the striated muscles. Embryos reaching other tissues fail to develop. It is about ten days before they reach the muscle. In the muscle they become encysted as oval lemon-shaped areas containing coiled up embryos; these areas are about 450 by 250 microns, and have a chitinous capsule. The hog may gain his infection by eating the meat of other hogs or rats. These rats eat scraps of pork at slaughter houses and become infected. Being cannibals, rats, when once infected, continue to propagate the infection."

Laboratory methods of diagnosis:—"Obtain specimens of the pork which has caused the trouble and examine for encysted trichinæ; or feed to white rats or rabbits and subsequently examine the diaphragm of these animals for encysted trichinæ or the intestine for adult trichinæ. Excision of a small piece of the deltoid of man may confirm the diagnosis. The best method is to take blood in 3 per cent. acetic acid, centrifuge, and examine for larvæ. During the diarrheal stage we may examine the stools for adult worms, in particular dead males or possibly actively motile embryos—these latter are about 90 by 6 microns. Always examine the blood for eosinophilia."—(Stitt's *Pratical Bacteriology*, etc.)

PHYSIOLOGY.

1. RESPIRATORY CHANGES IN THE LUNGS. *"Oxygen:* During a normal inspiration atmospheric air is drawn into the larger bronchi; here the tension of the oxygen is greater than the tension of that oxygen which is in the infundibula, where the oxygen tension in man has been calculated to be 13 per cent. of an atmosphere of oxygen. The gases in the infundibula, and consequently in the alveoli, are separated from the blood plasma in the lung capillaries by the flattened cubical epithelium of the alveoli and the endothelium lining the capillaries; it is believed that oxygen diffuses from the alveoli through the two kinds of epithelium into the plasma of the venous blood which has just arrived in the lung, and which is collected in the distended capillaries. Now, oxygen accumulates in the blood, which is consequently becoming rapidly arterial, until its tension rises to 38.5. It is obvious, therefore, that there must be another factor at work besides diffusion to account for this difference of oxygen tension. The epithelium which lines the alveoli is cuboidal in shape, and was originally derived from the epithelium lining the alimentary canal, and in function it is probably secretory. The inference to be drawn, therefore, is that some oxygen diffuses from the alveoli into the plasma of the lung capillaries so long as the oxygen in the alveoli is at a higher tension than that in the plasma; when, however, a state of equilibrium is reached, the cubical cells, possibly controlled by the vagi, begin to secrete oxygen from the alveoli into the blood plasma.

"Carbon-dioxide leaves the venous blood in the pulmonary capillaries and gets into the alveolar air, where

its tension is usually 5 per cent. in males and 4.7 per cent. in women and children. The tension of carbodioxide in venous blood is higher than 5 per cent.; so that it is by diffusion that the CO_2 leaves the venous blood and enters the air in the alveoli, and it is by a continuation of the process of diffusion that the CO_2 leaves the air in the alveoli and enters the bronchioles."—(Lyle's *Physiology.*)

Oxygen Secretion.—"Haldane is of the opinion that under some circumstances oxygen may be secreted from the alveolar air into the blood through the agency of the epithelial cells of the lungs. The condition on which he lays emphasis is that of diminished oxygen-pressure in the alveolar air, such as occurs in high altitudes. The disturbances produced at these altitudes, so-called mountain sickness, are now recognized to be due to lack of oxygen. Those who live for some time under such conditions gradually become acclimated, and Haldane believes that the essential factor in the acclimatization consists in the assumption of a secretory activity for oxygen upon the part of the lungs. His reason for this view is the discovery that the oxygen-pressure in the arterial blood under these conditions is greater than the oxygen-pressure in the alveolar air. As collateral evidence he cites the case of the swim-bladder in deep-sea fishes. The gas in this bladder is known to be nearly pure oxygen, and it may exist under a pressure of 100 atmospheres, although in the blood of fishes the oxygen-pressure cannot exceed 1/5 to 1/10 of an atmosphere."—(From Howell's *Physiology*)

2. "*Vitamines* have been shown to be of great importance in nutrition. The exact character of these substances has not been established. There are two distinct accessory food substances, one soluble in fats and called 'fat soluble A,' the other soluble in water and called 'water soluble B.' The substances have a rather wide distribution. The fat soluble vitamine is present in milk fat, egg yolk fat, beef fat, cod liver oil, 'oleo oil' margarines, cabbage, and alfalfa leaves, rye, and the seeds of flax, hemp, millet, and sunflower. The water soluble vitamines occur in milk, rice (unpolished), yeast, peanuts, pancreas, and kidney bean. Certain animal and vegetable products contain both the vitamines. Among these are whole milk, cotton seed, soy bean, the kernel of maize and oat, and the kernel and embryo of wheat. In order that a diet may be adequate for growth it must contain a satisfactory quota of these accessory food substances in addition to protein, proper in kind and amount, suitable inorganic matter and enough fat and carbohydrate to yield the required energy."—(Hawk's *Practical Physiological Chemistry.*)

3. "It may be assumed that the *function of the glomerulus* is to pass from the blood to the uriniferous tubules large quantities of an alkaline fluid which contains urea, chlorides, phosphates, sulphates, and under some circumstances sugar and other substances, in the proportion in which they occur in the blood. And that the *functions of the tubules are:* (1) To change the reaction of the glomerular fluid to acid. (2) To add to it certain substances by excretion, such as urea, uric acid, creatinin, urinary pigment, phosphates, and, under certain circumstances, water. (3) *To concentrate the urine*, by the reabsorption of much of its water and of some of its dissolved substances. These are reabsorbed somewhat according to their absorption power, *i.e.* sodium chloride readily, sulphates less readily, and urea not at all."—(Bastedo's *Materia Medica*, etc.)

4. *Function of the pituitary gland:* "The *anterior* lobe is concerned with the process of growth, hypertrophy leading to overgrowth of the skeleton, and partial removal to failure of development of the body as a whole and of the sexual glands. Extracts of the *posterior* lobe, when injected into an animal, have a direct action on plain muscle all over the body; they cause constriction of the arterioles and a rise of blood pressure, contraction of the muscular coats of the digestive tract and of the bronchioles, and contraction of the uterus. The extracts also produce an increased flow of urine, which was at first attributed to the presence of a substance having a specific effect upon the renal cells; it is probable, however, that the diuretic effect is merely an indirect result of the more rapid flow of blood through the kidney which follows the injection of the extract. Extracts of the posterior lobe increase the secretion of milk, and after the injection a larger amount of milk is formed by the animal in the course of twenty-four hours."—(Bainbridge and Menzies' *Essentials of Physiology.*)

5. At 85° Fahr., with a high relative humidity, there will be very slight loss of heat by evaporation and radiation. At 35° Fahr., under similar humidity, there will be a greater loss of heat from the skin.

"A much higher temperature may be borne in dry air than in air saturated with watery vapor. A shade temperature of 100° Fahr. in dry air is quite tolerable, while a temperature of 85° Fahr. in moisture-laden atmosphere may be oppressive. The reason is that in dry air the sweat evaporates freely and cools the skin, while in moist air, although according to Rubner the loss of heat by radiation and conduction is increased, the loss of heat by evaporation of sweat is diminished in a still greater degree. In saturated air at the body-temperature no loss of heat by perspiration or by evaporation from the pulmonary surface is possible; the temperature of an animal in a saturated atmosphere at 35° to 40° C. soon rises, and the animal dies."—(Stewart's *Physiology.*)

6. "The nutrition of the heart muscle, its irritability and contractility, depend on the blood supply derived from the coronary vessels. This is shown by the effects which follow its withdrawal. Ligation of both coronary arteries in the dog is followed by a diminution in the force and frequency of the heart-beat, and in a few minutes by complete cessation. Ligation of even a single branch of a coronary artery of the dog heart provided it supply a sufficiently large territory—*e.g.* the arteria circumflexa—is sufficient to cause arrest in at least 80 per cent. of animals (Porter). With the ligation of this vessel there occurs a gradual diminution in the force and frequency of the systole. As the power of coordinate contraction ceases the heart muscle frequently exhibits a series of independent contraction of individual fibers and cells known as fibrillary contraction. All the results which follow ligation are to be attributed in the light of experiment to the sudden anemia which is thus established. The removal of the ligature and the return of the blood will restore the nutrition and reestablish cordinate contractions."—(Brubaker's *Physiology.*)

7. "The *semicircular canals* are, through the vestibular nerve and the cerebellum, the most important agents in the preservation of equilibrium. When in a pigeon the horizontal canals are divided, the head moves from left to right and from right to left, with nystagmus and a tendency to revolve on its vertical axis. When the inferior vertical or posterior canals are divided the head oscillates from front to rear; the animal has a tendency to fall backward. A section of the superior vertical canal causes the head to oscillate from front to rear, with a tendency to fall forward. A section of all the canals is followed by contortions of the most bizarre nature. After a destruction of all the canals the animal cannot maintain his equilibrium. Similar phenomena have been observed in man in disease of the semicircular canals, known as Menière's vertigo. In the fixed position of the head there is equilibrium, but with each movement the varying tension of the liquid in the ampulla changes and irritates the hair cells."—(Ott's *Physiology.*)

8. *The mutual relations of the internal secretions of the pancreas, thyroid, and the chromaffin tissues as regards the mobilization of sugar in the organism.*—"The ductless glands may be divided into two groups according to the action of their hormones. There is (1) an *accelerator* group, and (2) an *inhibitory* group. The thyroid, pituitary, and suprarenals (chromaffin system) belong to the former, since it has been shown that all three increase protein metabolism, that the adrenals cause mobilization of the carbohydrates, and that the thyroid causes increased fat absorption. To the inhibitory group belong the pancreas and parathyroids, since both retard protein exchange, and both restrain the mobilization of carbohydrates, in each instance the pancreas being the more powerful. Evidence tends to show that the hormones of the pancreas and adrenals are antagonistic in their action so far as carbohydrate metabolism is concerned. Both profoundly influence the mobilization of glycogen in

the liver. The former retards glycogenolysis, whereas the adrenals accelerate the mobilization of liver glycogen—that is, hasten glycogenolysis. In health and when both glands are functioning normally, the action of each hormone balances the other and the glycogenic function of the liver is carried on normally, no hyperglycemia occurs and consequently no glycosuria."—(From Osler's *Modern Medicine.*)

MEDICAL JURISPRUDENCE.

1. *Three causes of sudden death:*—(1) Lightning; (2) Status lymphaticus, and (3) asphyxia (as by strangulation).

Death may follow *lightning* so instaneously as not to modify the position which the body held at the time of the shock; or it may follow later as the result of burns and lacerations; it may be due to the shock to the brain and nervous system.

Post-mortem appearances: "In those cases of sudden death by lightning in which the body is left in the position occupied at the time of the shock post-mortem rigidity comes on at once. In other cases it may be slower in its onset, but usually is rapid as compared with death from ordinary causes. The conditions found after death from electricity are not consistent; neither are they such as in unknown cases would establish the cause of death. Many observers have reported the rapid following of decomposition, but there seems in fact to be little evidence that such is the fact. The heart may be filled with blood, which may be liquid or clotted. The blood is usually dark, but a case has been reported in which it was of a 'rosy, vermillion' color. There is usually a passive congestion of the various organs, including the brain, and small hemorrhages into its substance have been found. Small superficial hemorrhages are usually found scattered over the surface of the lungs and heart."—(Dwight's *Medical Jurisprudence.*)

In *status lymphaticus* there will be found hyperplasia of spleen, thymus, and lymphatic glands, with hypoplasia of the heart and aorta.

In *death by strangulation:* The blood is of a dark color, owing to complete reduction of the hemoglobin. The proportion of carbonic acid is increased, and owing to its excess the blood coagulates slowly or imperfectly; hence it remains fluid or forms few and soft coagula. The large veins, the pulmonary artery, and the cavities of the right side of the heart may be distended with dark fluid blood, but this is by no means necessarily the case. The left side is usually empty or nearly so. The lungs may be congested, but are often pallid and anemic, though the dependent parts usually exhibit appearances of hypostatic engorgement. The abdominal viscera, especially the kidneys, are often congested. The appearance of the brain varies; it may be anemic or more or less congested. Special signs characterize special modes of causation of asphyxia.—(From Quain's *Dictionary of Medicine.*)

2. *Evidences of a burn.*—Redness, blisters, destruction of cuticle, and subcutaneous tissue, blackening of the skin, scorching of the hair, line of demarcation between injured and uninjured parts, cracks or fissures in the skin.

Burns by flame are specially characterized by scorching of the surface. Hairs upon the part actually burned are scorched, and usually also those in the vicinity of the burned patches. Such conditions could not result from scalds by hot water, boiling oil, or from a hot body only.

Burns by petroleum or its derivatives resemble the burns from flame, except that the injured portions of the body are not only scorched but blackened and are usually burned more severely than by flame alone, as the clothing holds the burning substance in contact with the parts. The odor of the agent is also very noticeable.

Burns by acids. The eschar which results is not dry and leathery, as in a burn by heat, but soft and readily sloughing away. There is no redness around the site of the injury, the color of the burn being uniform, and no blisters are formed. There is no blackening of the skin, and the hairs are not scorched. Nitric acid produces a yellow stain, sulphuric acid a dark brown, and hydrochloric acid a brownish yellow stain.—(From Witthaus and Becker's *Medical Jurisprudence.*)

Cicatrices from burns.—"A superficial burn in healing produces a broad, irregular cicatrix, varying with the form of the burning body. If the burn has extended to some depth below the cutis the cicatrix is deep, and has a rounded margin; but in the depression, it is irregular and contracted in proportion to its depth. Caustic solids produce cicatrices with regular edges, as the corrosive substances easily penetrate uniformly through the deep layers of the skin. Caustic liquids produce only superficial marks unless they have been allowed to penetrate deeply when by the destruction of parts they may give rise to deep and irregular cicatrices. When the cutis is destroyed an indelible cicatrix remains, whether it is the result of a burn from a heated solid or from the chemical action of a highly corrosive liquid."—(Taylor's *Medical Jurisprudence.*)

3. *Insanity*, legally speaking, is a condition of mental unsoundness and irresponsibility, by reason of which a person is unable to understand the nature of his act or to pass a fairly rational judgment on its consequences to himself and others, and is not a free agent as far as the act is concerned.—(Dana's *Nervous Diseases.*)

Paranoia "is a form of insanity which comes especially under the class of degenerative diseases. It is essentially characterized by a delusion or delusions of a fixed and systematized character. They are usually indeed of one kind, and the disease has perhaps for this reason been called monomania. This is, however, an unfortunate term, as we find this symptom not infrequently in other forms of insanity, as melancholia, where we always observe decidedly fixed ideas of depression. The main fundamental characteristic of this disease is a delusion which has become a part of the belief of the individual, and which he believes himself able to explain and defend."—(Witthaus and Becker's *Medical Jurisprudence*, etc.)

Some of the criteria of insanity.—Various anatomical stigmata (chiefly noted in palate, skull, ears and teeth), lessened cutaneous sensibility, defects in sight and hearing, tooth-grinding, facial grimaces, and other tics, agitated movements, anxious, apprehensive expression, apathetic and listless movements, with hanging of the head, katatonic states and strange attitudes, senseless resistance to requests or negativism, peculiar repetition of certain movements, muttering, senseless laughter, verbigeration, hallucinations, illusions, and delusions; confusion, retardation, or difficulty of thought; maniacal excitement and delirium; disorientation, weakness of memory or will power; obsessions, fixed ideas, and compulsions.—(From Dana's *Nervous Diseases.*)

Post alcoholic psychosis—"Persons who have for long periods of time continuously and excessively indulged in alcohol may develop, and generally do, a condition of mental weakness which to a certain extent simulates paresis. If these patients have not had syphilis, however, it is not a true paresis. The patients become weak-minded, feeble in judgment, poor in memory, their moral instincts get out of control, and acts of extraordinary selfishness, bestiality, and besottedness are manifest. They gradually become more enfeebled, and finally enter a condition of dementia if they are not carried off by some intercurrent disease, as is often the case. These cases, however, do not present the physical symptoms of paresis. They do not have the speech disturbances, the paralyses, or the apoplectiform seizures that characterize the true disease, and if they can be kept from alcohol they may remain in a state of partial dementia for many years."—(Dana's *Nervous Diseases.*)

4. If the patient died *from the inhalation of gas*, his blood will be of a cherry red color, and will give the characteristic bands on spectroscopic examination. The skin and mucous membranes will be of a reddish color, almost life-like, rather than of a blue or purple lividity.

In *death from strangulation* there may be marks on the neck; the face will be livid, swollen, and perhaps almost black; the pupils dilated; the lungs emphysematous, and the blood characteristics mentioned above will be absent.

5. *Motives for feigning disease.*—(1) Soldiers, sailors, and prisoners may feign disease in order to shirk their duties or to secure a more comfortable mode of life. (2) Civilians may feign disease in order to shirk jury duty, appearance in court, or military service. (3) Such motives as fear, gain, notoriety or laziness, and espe-

cially the idea of extorting money from individuals, corporations, etc., may induce persons to feign disease.

Feigned deafness may be detected by making a noise at an unexpected moment, or by a sudden change in the examiner's voice; administration of ether may enable one to detect the fraud, as before the culprit regains thorough consciousness he is apt to forget his rôle and "give himself away."

Feigned ankylosis of the knee may sometimes be detected by the sudden administration of a severe electric shock, or by the use of anesthetics. In a bony ankylosis there will be a complete loss of movement under anesthesia. In a true ankylosis there will be atrophy of the muscles, which will not be noticeable in the feigned condition.

Self-inflicted carbolic acid burns may harden the skin and give it a corrugated appearance; sometimes they produce a whitish color, rather than the color indicated in Question 2 as produced by other acids. If the case is quite recent the urine may show a dark green or smoky color.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	S. W. Welch, Montgomery	Montgomery...Jan. 13
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix	Phoenix.....Oct. 7
Arkansas	T. J. Stout, Brinkley	Little Rock....Nov. 11
California	C. B. Pinkham, Sacramento	Sacramento....Oct. 20
Colorado	David A. Strickler, Empire Building, Denver	Denver.....Oct. 8
Connecticut*	Chas. A. Tuttle, New Haven	New Haven....Nov. 11

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Death from Overdose of Antimony.—The great employment of antimony in various tropical parasitic affections such as leishmaniosis and granuloma venereum naturally is attended by the risk of fatal doses. In an abstract from *La Pediatria* we find that a young man with ulcerative granuloma, an Australian, succumbed after a series of intravenous injections of tartar emetic of increasing strength. The leading end symptoms were vomiting, delirium, and fever. The autopsy showed fatty degeneration and focal necrosis of the liver and acute interstitial nephritis.

Miscellany.

Failure of German Medical Propaganda in Spain.—A contributor to the *Journal de médecine de Bordeaux* for July 10 intimates that France was badly out of touch with Spain during the war under the impression that the latter country was Germanophile. This view, which was naturally shared by the French medical profession, has been shown to be an error. German money had indeed bought up the Spanish press, and a hundred thousand rabid Boches were active in Spain. There was, however, a corresponding body of French and Francophiles which instituted a counter propaganda, and during 1918 this effort began to bear fruit. The response, when it began, was prompt and thorough, and the medical profession were among the first to assert their French sympathies. It was apparent that during the years before the war the Germans had been making intensive efforts to replace the old Latin culture with their own product. A swarm of scientific and other German books were turned loose in Spain and German professors lectured in the Spanish universities. Spanish students were recruited for the German universities with the implication that the Teuton represented the last word in medical process.

Only a very small number of Spaniards entered the French universities during the war; these not only found grand opportunities for study but heard the French professors do full justice to the latest German discoveries. In other words, the short journey to the French medical centers gave them practically all they could acquire by a sojourn to the more remote Berlin and Vienna. Despite all the advantages of the German invasion of books, instruments, electrical and *x*-ray apparatus, the Spanish medical profession is still Francophile at heart, as was the case before the war. This is well shown by statistics, for of the more than 18,000 physicians in the entire Iberian peninsula not over five per cent. have formally pronounced themselves Germanophile. The nature of the 816 signatures of the latter persuasion shows only too plainly that many of them were dictated by Germanophile superiors. Hence it is a mere legend—the Germanophile bent of the Spanish medical profession.

Human Nature in Aphorisms.—Since Marcus Aurelius and in later centuries La Rochefoucauld, Chamfort, Rivarol, and others have sought to reduce life to axioms there have been few imitators, although such aphorisms have been culled from the writings of many great philosophers, thinkers, and men of action. The field has been pretty well exhausted and exploited and it takes a certain hardihood to enter it. Dr. Charles Fiessinger, a French physician, has made this attempt in a work entitled "Formules d'Expérience Humaine," which is briefly reviewed in the *Journal de médecine et de chirurgie pratiques* for July 10. According to the reviewer, the style adopted is that of Epictetus and Marcus Aurelius and the content the discussion of men, women, scientists, and institutions. The sources are personal, the author speaking of what he has seen and the reflections set in motion by his own experience. The reviewer praises the chapter on scientists as the most original.

ANGINA PECTORIS.*

BY HERMON C. GORDINIER, M.D.,

TROY, N. Y.

ANGINA PECTORIS may be defined as a sympton complex characterized by pains of a paroxysmal character often recurring, of a mild or of a severe agonizing type usually having its early localization in the sternal region, either sub-manubrial sub or retro-sternal in character and frequently associated with a terrible sensation of impending dissolution, organic or functional in nature.

Historical.—To Heberden belongs the honor of first directing attention to the complex of symptoms which he named angina pectoris. In his first communication read July 21, 1768, he published his experience spread over more than 20 years which contained a most accurate account of the symptoms and post-mortem findings. Rougnon and Morgagni, however, long before had described several cases. Fothergill was the first to publish coronary artery diseases in subjects dead of angina pectoris, while the association of the symptoms of angina pectoris with coronary artery disease was first demonstrated by Sir William Jenner. The association with the various types of aortitis was first demonstrated by Corrigan and Sir Clifford Allbutt, while Lauder Brunton performed a most humane service by introducing the nitrites for the relief of the symptoms of this disease.

Pathology.—Angina pectoris has pathological associations which are so frequently observed that they appear to have a very definite relation to it. The inorganic or functional type shows no naked eye changes and probably has for its cause sudden increased intra-aortic pressure from general vasomotor spasm. Cases of angina which are fatal usually show associated changes in the aorta-coronary area, the suprasigmoid part of the arch, the coronary arteries, myocardium, and general vascular tree. Hence the common autopsy finding is disease of the beginning of the aorta, at its root, about the sinuses of Valsalva, aortic valve disease luetic mesaortitis or aortitis due to acute infections; atheroma, atherosclerosis often comprising the origin of the coronaries, general sclerosis of the coronaries, with remakable thickening and tortuosity with partial or complete obliteration of their calibre, with or without calcification and not rarely thrombic formation. It must be remembered, however, that thickened, tortuous sclerotic coronaries which are ofttimes exceedingly narrow, are frequently found at autopsy in patients who have never suffered with angina; and on the other hand, a number of sufferers have died of angina whose coronary arteries were found patent and otherwise normal.

Verdon found in a series of 283 cases of angina, the coronaries healthy in 43 per cent. of the fatal cases. Tacchi in 70 cases found coronary artery disease in 38, while Sir John Forbes found diseased coronaries in 16 of 45 fatal cases.

Small aneurysms of the ascending portion of the aortic arch, or of the sinuses of Valsalva compressing or not, the mouths of the coronary arteries, have been found in mortal cases. Infectious aortitis is not a rare pathological finding, especially following rheumatic and scarlet fever, influenza, variola, diptheria, etc. I have seen three cases of acute pericarditis in which the exudate was largely basal, associated with severe stenocardia, great pallor, faintness, and sternal pain radiating to the left shoulder and down the left arm. Only this summer I had under my care a boy nine years of age who died suddenly with a severe anginoid attack while suffering from rheumatic pericarditis; the friction rub having persisted at the base of the heart. No postmortem was allowed. Perhaps the most frequent association with angina pectoris is syphilitic aortitis, a true mesaortitis due to primary changes, endarteritis of the vasa vasorum. This form of pathological change, as you are well aware, is frequently localized to the suprasigmoid part of the aortic arch, including the aortic ring valvular apparatus, and mouths of the coronaries. In many of the fatal cases of angina ,the myocardium shows degenerative changes characteristic of syphilis. These changes are often secondary to coronary artery disease and may be due to a diminution of the blood supply to various areas of the myocardium.

Etiology.—Angina pectoris is by no means a rare disease. Naturally, it is more often observed by the general practitioner and consultant than the hospital physician. I have seen but five cases in the Samaritan Hospital in a medical service of over twenty years, while I have observed considerably over 100 cases in private and consultation practice. I remember of having seen but two cases in the wards of several hospitals of this country and in Europe. While most authors state that this disease is more prevalent among the well to do, my experience has been that the cases are about equally divided.

The age of the onset is variable; most of my cases have been between the ages of 45 and 65. The earliest cases of anginoid pain, observed by me, were in girls at 8 and 13 years of age, and a boy

*Read at the twentieth annual meeting of the American Therapeutic Society, at Atlantic City, June 6 and 7, 1919.

of 9, all cases of basal pericarditis. The earliest adult was a male 35 years of age who died in his first attack. His father also died of angina while under my care, having previously suffered with several attacks of a mild character.

Dr. H. Stewart has published a case of angina pectoris with aortic valve disease in a boy, age 7½ years. The angina came on toward the conclusion of a severe rheumatic fever, first indefinitely then in frequent and typical attacks. There was no cyanosis, no dyspnea, but sudden pallor, pain, and great anxiety. Sir Clifford Allbutt describes a case of a girl, 12½ years of age, who at the end of a rheumatic attack, complained of intense retrosternal pain and constriction, with pain down the left arm, who died in an attack.

Last summer I attended a boy with severe rheumatic pericarditis with effusion, who suddenly complained of retrosternal pain and pain in both shoulders and down both arms, which required stiff doses of morphine to relieve, who expired suddenly in a subsequent attack of a similar nature.

Of Osler's 268 cases, 30 were under nine years; forty between 30 and 40 years; 59 between forty and fifty years; 81 between fifty and sixty; 62 between sixty and seventy years; 13 between seventy and eight years, and 3 above eighty years.

Heredity undoubtedly exerts a prominent influence in the evolution of this complex of symptoms. Certain families are prone to generative vascular changes, both general and local. Their vascular rubber early loses its resiliency and inclines to early decay. How often do we in turn see several members of a family affected with focal or general arteriosclerosis with hypertension, with or without angina pectoris. Many cases are on record where this affection could be traced through two or more generations. Osler, Latham, Gardner, and Allbutt have reported surprising examples of such heredity, and I have seen angina pectoris in brother and sisters, in two brothers, in both father and son, and mother and daughter.

Neuburg found a definite family relation of 20 of his 143 cases of angina. Professional men seem rather prone to this affection—think of such savants as John Hunter, Charcot, William Pepper, and Nothnagel all perishing with this disease. As you well know, a number of our local confrères have succumbed to it.

Women are much less frequently affected with true angina than are men. I have seen but seven cases in women and considerable over a hundred in men. Osler saw but one woman in his first 48 cases. The explanation possibly may be a more quiet life, lack of physical or mental strain, and a much smaller margin of syphilis, which after all plays a most important rôle in its production. Then again, if angina was a mere neurosis as many have insisted, it would be much more common among the gentler sex.

The acute infectious diseases more notably, acute rheumatic and scarlet fever, grippe, typhoid fever, variola, diphtheria, and septic infections, predispose to angina because of the not infrequent complication of infectious aortitis. Sansom reports two cases with autopsies following grippe, with patches of suprasigmoid aortitis which had involved the mouths of the coronary arteries. In this regard, Thayer's observation of the frequency of the arterial changes in typhoid fever are very interesting, and Flexner has found in acute aortitis lying within the vascular wall, many other organisms than the *Spirochæta pallida*.

Of all the causes, syphilis stands preeminent; it is doubtless the most common, and is the causal factor, either hereditary or acquired, in many of the earlier and most of the cases of middle life, and of not a few cases in later life.
